LET WISDOM GUIDE

THE BRITISH JOURNAL OF PSYCHIATRY

January 1987 Vol 150

Acc;
15.12.87

ISSN 0007–1250

Published by authority of
The Royal College of Psychiatris

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al, British Medical Journal*, 7 May 1983, **286**, 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that . . .'

DURKHEIM, E. (1897) Le Suicide. Paris. Translate (1952) as Suicide: A Study in Sociology, by J. A Spaulding & C. Simpson. London: Routledge & Kega Paul.

KENDELL, R. E. (1974) The stability of psychiatri diagnoses. British Journal of Psychiatry, **124**, 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (197 Education, Health and Behaviour. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognos and treatment. In Pathology and Treatment of Sexu Deviation (ed. I. Rosen) Oxford: Oxford Universit Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols an Abbreviations: A Guide for Biological and Medical Edito and Authors* (3rd ed. 1977), £2.00, available from th Publications Office of the Royal Society of Medicine. Term or abbreviations which might not be understood by th average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separat sheet, with an adequate heading; table and heading should b self-explanatory without reference to the text. The desire position of the table relative to the text should be indicated i the left margin.

Figures should be individual glossy photographs, or othe camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

The "Sissy Boy Syndrome" and the Development of Homosexuality
Richard Green, M.D.
Based on a fifteen-year study of two groups of young boys and their parents, this pathbreaking book by psychiatrist Richard Green is the first to trace the development of homosexual and heterosexual behaviour from childhood to adulthood. *Illus.* £30.00

Freud and the Rat Man
Patrick J. Mahony
with a foreword by Otto F. Kernberg, M.D.
A noted Freud scholar re-examines the famous Rat Man case, disclosing for the first time the patient's true identity, uncovering crucial discrepancies between Freud's process notes and his published report of the case, and demonstrating the link between Freud's use of language and his treatment. £20.00

Melancholia and Depression
From Hippocratic Times to Modern Times
Stanley W. Jackson, M.D.
The first comprehensive history of depression in English. Dr. Jackson discusses the ways in which depression has been defined over time, the explanations proffered for its causes, and the various approaches used to treat the sufferers. £35.00

Social Origins of Distress and Disease
Depression, Neurasthenia, and Pain in Modern China
Arthur Kleinman, M.D.
A unique examination of the multilayered relationship between neurasthenia, depression, and physical symptoms, based on the author's extensive research in the People's Republic of China — the first research by an American psychiatrist in China since 1949. £20.00

Interpreting Lacan
Psychiatry and the Humanities, Volume 6
edited with an introduction and epilogue by Joseph H. Smith, M.D., and William Kerrigan
"The English-speaking reader wanting a balanced but critical exposition of Lacan ... will be grateful for *Interpreting Lacan.*" — *American Journal of Psychiatry.*
May Paper, £9.95

MRCPsych CANDIDATES

Invaluable book now available containing 5 Practice Exams for MRCPsych prelim Examination.

Book contains essential advice on exam technique, 300 MCQs, self-marking system, correct answers, teaching explanations, revision index and book list.

Books are sent by return of post, first class mail. Order now by sending cheque or visa/access number for £7.95 plus p+p total £8.70 to PASTEST, FREEPOST, Dept P. 304 Galley Hill, Hemel Hempstead, Herts. Tel: 0442-52113

Mental Health Foundation
RESEARCH GRANTS

The Research Committee of the Foundation exists to foster and support research in all fields bearing on mental health, mental illness and disorders of mental development.

The Committee meets twice a year to award **RESEARCH GRANTS TO PROVIDE SCIENTIFIC ASSISTANCE, EXPENSES** or **EQUIPMENT** for research workers.

Closing Dates:
March 1st for Meeting in May
September 1st for Meeting in November

For Grant application forms and further details apply in writing to:

The Honorary Secretary,
The Research Committee,
Mental Health Foundation,
8 Hallam Street,
London W1N 6DH

SYMPOSIUM ON PSYCHIATRIC ASPECTS OF THE FACE

The face is so important for communication of emotions that it is bound to be a fascinating topic of study for psychiatrists.

In this symposium we will be exploring facial expressions in relationship to emotions, including distortion of expression in relationship to psychopathology. Other aspects will include disorders of facial movement that occur consequent on treatments and abnormalities of facial recognition secondary to cerebral lesions.

Programme

The Face – Its Clinical Relevance	Dr E. M. R. Critchley
Evaluation of Emotion by Non-Verbal Expression	Professor Paul Ekman
The Face – An Anthropologists's Viewpoint	Dr R. Littlewood
Disorders of Facial Recognition – Prosopagnosia	Professor H. D. Ellis
Disorders of Facial Recognition – Misidentification Syndromes	Dr S. Lewis
Disorders of the Face in Psychiatry – Dysmorphophobias	Dr T. M. Reilly
Disorders of the Face in Psychiatry – Movement Disorder	Dr A. J. Lees

This one-day Symposium will be held on:
Friday 6 March 1987
at
The Royal Society
6 Carlton House Terrace
London, SW1Y 5AG

The cost of registration will be £20 (£10 for junior medical staff.)
For further details of the Symposium and for registration forms, please contact:
Diane Carter, Charter Clinic, 1/5 Radnor Walk, London, SW3 4PB. Tel: 01:-351 1272

Charter Clinics

Applications and nominations are invited for the position
of

Director of Research in Child and Adolescent Psychiatry

in the
Division of Child and Adolescent Psychiatry, Department of Psychiatry, Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, New York

The Division has strong and extensive clinical and teaching programs in five centers all under one overarching administrative structure. The Department, of which the Division forms a part, has strong research programs in biological psychiatry, psychotherapy evaluation, and social psychiatry. With this appointment, we are seeking to expand our research activities in child psychiatry and to integrate them under one leadership. The successful candidate will be expected to:

1. Carry forward his/her own research activities with a major focus in psychopharmacology/biological psychiatry and/or epidemiology particularly welcome, but not to the exclusion of others,
2. Integrate, stimulate and oversee child psychiatry research activities in the several centers of the Division,
3. Integrate, stimulate and come to play a major direct role in the teaching, Division-wide, of research related material.

The position is full-time for an M.D. or a Ph.D. Academic appointment and salary commensurate with experience. Submit by February 15, 1987 to:

Everett Dulit, M.D., Director, Division of Child Psychiatry, Albert Einstein College of Medicine/
Montefiore Medical Center, 111 East 210th Street, Bronx, New York 10467

PROVINCE OF BRITISH COLUMBIA, CANADA
MINISTRY OF HEALTH

PSYCHIATRISTS

Mental Health Services in British Columbia has recently announced the amalgamation of their primary in-patient psychiatric hospitals (Riverview and Valleyview). This new hospital is organized into adult and geriatric divisions and invites qualified applicants (FRCPC or MRC Psych) to direct a broad range of multi-disciplinary programs, including assessment, acute care, continuing treatments and community preparation for a total patient population of approximately 1200. Research and educational programs have been developed as an integral part of the activities of each division.

Both salaried and contract appointments are available with potential earnings up to $90,000 Cdn. per annum. Facilities are located twenty minutes east of Vancouver.

Reply with a curriculum vitae to Dr. J. E. Runions, Clinical Director, Riverview Hospital, 500 Lougheed Highway, Port Coquitlam, B.C. Canada V3C 4JC immediately.

Institute of Family Therapy

(London)

TRAINING AND TEACHING PROGRAMME 1987/88

The Institute of Family Therapy (London) offers a series of courses, ranging from a **four-year, part-time Training Programme**, to **one and two day workshops**, for professionals working in related fields, i.e. Social Work, Clinical Psychology, Psychiatry, Nursing.

INTRODUCTORY COURSE IN FAMILY THERAPY

The Introductory Course is focussed towards relevant professional staff who want to develop their interest in and explore work with families. The concepts underlying work with the family as a system and the broad principles of systems theory will be presented.
30 sessions of 3½ hours on Tuesday afternoons.

CLINICAL TRAINING PROGRAMME

FAMILY THERAPY TRAINING, PART I
This course is open to participants who have completed an Introductory Course in Family and Marital Therapy. The Course offers consultation to members' work in their agency setting and development of their therapeutic skills.
30 sessions of 3½ hours on Wednesday evenings.

FAMILY THERAPY TRAINING, PART II CLINICAL SUPERVISION
30 sessions of 4 hours over 2 years: supervision groups, theoretical seminars, tutorials and lectures. Participants will normally be required to complete Family Therapy Training, Part I before clinical supervision.

The Training Programme Commences each year in October.

DAY WORKSHOPS AND SHORT COURSES

The Institute offers one and two day workshops and short courses focussing on specific issues. The Spring term workshops will focus mainly on Life Cycle and Family Breakdown Issues.

SPECIAL EVENTS

ETHNICITY AND FAMILY THERAPY—a series of evening seminars in March, May and June 1987 to explore the relationship between culture, family structure life cycle issues and the implications for family work.

VIDEO TAPES

The Institute has a varied video library of tapes available for hire. The revised Teaching Tape Catalogue is now available. The current list of tapes for hire includes work by British, American and European therapists and is an invaluable teaching resource for students at all levels of experience.

For further details on any of the above please write, enclosing an SAE, and stating which details you require to:
The Administrator, Institute of Family Therapy (London), 43 New Cavendish St, London W1M 7RG.

Mental Health Foundation

FELLOWSHIPS

Applications are invited for Mental Health Foundation Fellowships from suitably qualified persons wishing to pursue Full-time Research Work bearing on problems of mental health, mental illness or mental handicap, whether in clinical psychiatry or in one of its supporting sciences.

Both Junior and Senior Fellowships are offered in the salary ranges of Junior/Senior Lecturer, Junior/Senior Registrar, according to seniority and experience, plus superannuation. However, Senior Fellowships are only awarded under exceptional circumstances, e.g., as a temporary measure prior to the Fellow taking up a permanent career post. The appointments, which are also open to candidates from overseas, will be for up to three years in the first instance and in exceptional circumstances may be extended to five years. Interviews will be held in May in London and the Fellowships will be taken up between the following July 1st and March 31st. Overseas candidates, if shortlisted, must attend for interview at their own expense.

Closing date: March 1st.

Application forms and further information may be obtained from

The Secretary,
The Research Committee,
Mental Health Foundation,
8 Hallam Street,
London W1N 6DH

Psychiatry in Medical Practice

DAVID GOLDBERG,
FRANCIS CREED
and **SIDNEY BENJAMIN**

In a straightforward and practical way, *Psychiatry in Medical Practice* sets out the knowledge which students need to understand the common psychiatric disorders and psychological problems they are likely to encounter in general practice.

CHICKEN OR EGG?

Is your patient drinking because he has problems — or does he have problems because he is drinking?

The answer may be difficult to establish, particularly in the presence of continuing alcohol abuse.

An accurate assessment of the contribution of the various factors involved is essential in devising the most appropriate treatment programme for each individual.

The T.O. Prichard Unit at St. Andrew's Hospital offers detailed assessment and a full range of treatment facilities for all degrees of alcohol dependence.

For further details write or telephone:-

NEW BOOKS *from Croom Helm*

VARIANT SEXUALITY

Edited by Glenn D. Wilson, Institute of Psychiatry, University of London

Presents contributions from major international authorities reviewing major themes in variant sexuality, and presenting new research. Genetic and evolutionary arguments are used, and topics such as psychoanalytic theories, fetishism, sadomasochism and transsexualism are reviewed.

£25.00 0-7099-3698-2 272 pages December 86

LIAISON PSYCHIATRY

Joan Gomez, Consultant Psychiatrist, Westminster Hospital, London

This book introduces a rapidly growing field by examining the scope and organisational issues of liaison psychiatry and its role in psychiatric patients with organic disease, psychosomatic disorders, emotional reactions to physical disease, terminal illness, etc. Useful for MRCPsych trainees and qualified staff.

£22.50 hbk 0-7099-1190-4 288 pages January 87
£10.95 pbk 0-7099-1191-2

PSYCHIATRIC EPIDEMIOLOGY: PROGRESS AND PROSPECTS

Edited by Brian Cooper, Institute for Mental Health, Mannheim, West Germany

Presents new data and reviews current knowledge and ideas in this field. The book consists of edited papers from the World Psychiatric Association symposium held in Edinburgh, September 1985.

£29.50 0-7099-4814-X 416 pages February 87

PRACTICAL PSYCHIATRY OF OLD AGE

John P. Wattis, Consultant in the Psychiatry of Old Age, St James' University Hospital, Leeds, and Mike Church, Clinical Psychologist, Sheffield

'It is uncommon to find a textbook that fulfils its stated aim so delightfully. Wattis and Church combine sound clinical principles with a wide knowledge of the growing number of publications to produce an eminently practical guide to the psychiatry of old age ... this book will become very popular.' *British Medical Journal.*

£19.95 hbk 0-7099-3643-5 208 pages June 86
£ 8.95 pbk 0-7099-3644-3

TRANSCULTURAL PSYCHIATRY

Edited by John L. Cox, Professor of Psychiatry, University of Keele

Probably the first substantial British text to review psychiatric illness across cultures, at a level suitable for both mental health professionals and students. The book covers a field which is commanding increasing attention as societies become more multicultural.

£29.50 0-7099-3428-9 352 pages June 86

THE THERAPIST'S THESAURUS: A CARTOON GUIDE

Robert Wilkins, Child Psychiatrist, Reading, and Penny Loudon, Family Therapist, Norwich

This book pokes gentle fun at the psychiatric penchant for jargon, with nearly 200 cartoon drawings of 'alternative' definitions of common psychiatric terms.

£ 4.95 pbk 0-7099-3677-X 96 pages September 86

KEY CASES IN PSYCHOTHERAPY

Edited by Windy Dryden, Goldsmiths' College, University of London

Written by leading psychotherapists from the UK and USA, this book shows how these therapists grappled with cases which challenged their ideas about the theory and practice of psychotherapy and how they have revised these ideas as a result.

£22.50 0-7099-4501-9 272 pages March 87

SOLVENT ABUSE: THE ADOLESCENT EPIDEMIC?

Joyce M. Watson, Vice-President, Re-Solv, Glasgow

Based on detailed research by the author in the Strathclyde region to assess the characteristics of abuse and abusers, the author also reviews the world literature, so that the book will serve as a major reference source.

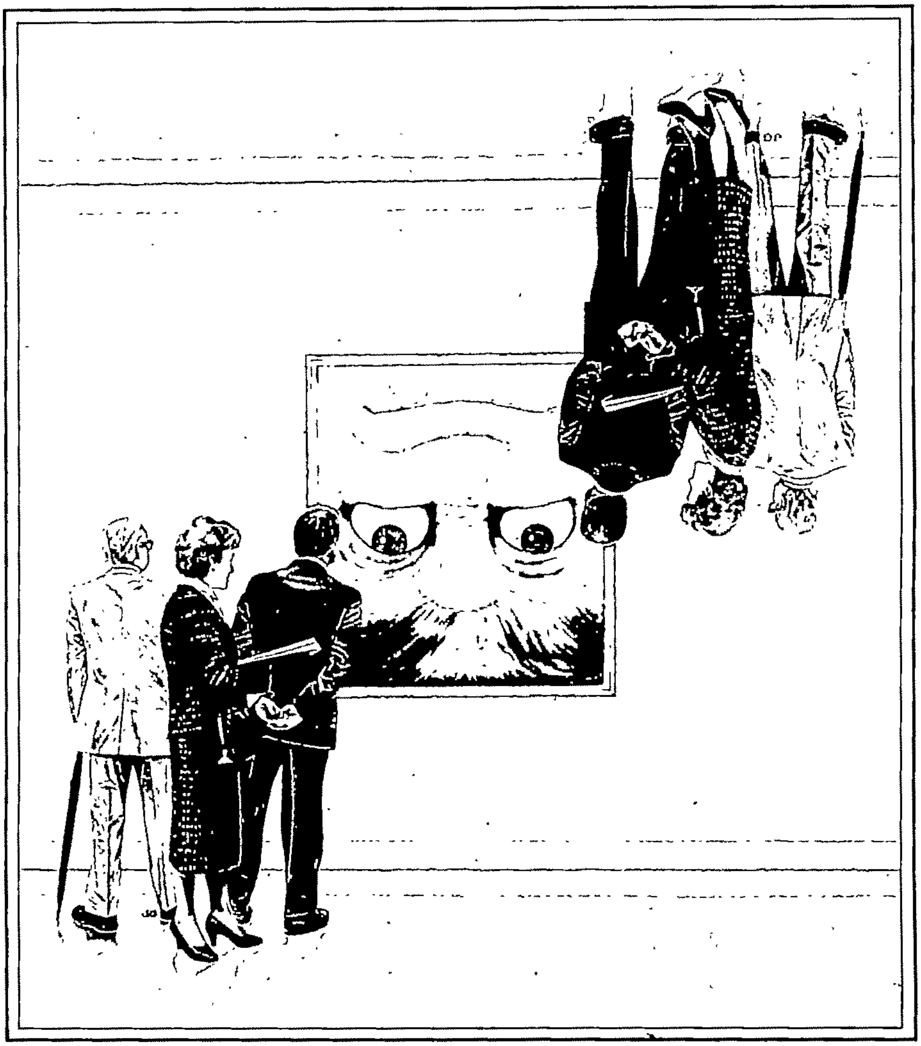
Modecate Abbreviated Prescribing Information. Indications: Treatment of psychotic disorders. **Dosage – Modecate injection 25mg/ml.** Most patients are successfully maintained within the dosage range 12.5mg (0.5ml) every five weeks to 100mg (4ml) every two weeks. For full dosage information see Data Sheet. **Modecate concentrate injection 100mg/ml.** Adult patients found to require larger volumes of Modecate 25mg/ml may be transferred directly to the equivalent dose of Modecate concentrate on the basis that 1ml Modecate concentrate is equivalent to 4ml Modecate. **Contra-indications.** Patients with marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, or severe cardiac insufficiency. **Precautions.** Care should be taken in patients, particularly the elderly, who exhibit marked extrapyramidal reactions to oral phenothiazines. **Side effects.** Mainly extrapyramidal reactions. Drowsiness, lethargy, dryness of the mouth and mild hypotension may occur. **Product Licence No's and Prices. Modecate injection 25mg/ml.** PL 0034/5046. 10 x 1ml ampoule £25.20 **Modecate concentrate injection 100mg/ml.** PL 0034/0189. 10 x 0.5ml ampoule £49.99 10 x 1.0ml ampoule £48.86. Modecate is a Trade Mark of E. R. Squibb & Sons Ltd. Further information available from: Technical Services Department, E. R. Squibb & Sons Ltd, 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. Tel: 01-572 7422.



TRIED AND TRUSTED

19 years ago, E. R. Squibb & Sons helped lead a revolution in the community based treatment of schizophrenia when they introduced the depot neuroleptic concept.
Since then worldwide clinical experience has confirmed the efficacy and safety of Modecate in over 800,000 patients.
Modecate is now regarded by many psychiatrists as the standard depot neuroleptic.

MODECATE®
25 mg/ml
100 mg/ml
FLUPHENAZINE DECANOATE

Modecate is available in two strengths, allowing a wide dosage range with convenient injection volumes.
Most patients can be controlled with an injection at intervals of 3 weeks or more.[1]
Modecate is less expensive than other depot neuroleptics when comparing equipotent doses.

Lecture

Changes in the Incidence of Schizophrenia?

The Fifty-ninth Maudsley Lecture delivered before the Royal College of Psychiatrists, 15 November 1985

ERIK STRÖMGREN

In general, results of epidemiological studies on schizophrenia performed during the last century have the remarkable feature that no significant differences in expectancies and incidences have been found, neither between different populations nor over time. Recently, however, some studies have tended to show a noteworthy decrease in the incidence, as measured by statistics of first admissions. Possible sources of error are discussed, partly on the basis of recent Danish investigations. Although it is uncertain whether a true change in the incidence of schizophrenia has occurred, one feature is becoming evident: under modern treatment and care of-schizophrenics the natural history of the disease is becoming increasingly different between the two sexes. This fact, in combination with one of the hardest facts in schizophrenia research, namely the higher age of onset in females, may be useful starting points for hypotheses on aetiology, or at least necessary components of such hypotheses.

One of the most serious concerns of psychiatrists is undoubtedly our ignorance of the aetiology of schizophrenia. What we know with certainty is only that genetic factors play a role. The results of family studies, twin studies and studies on adoptees leave no doubt about that. On the other hand, twin studies have demonstrated that the genetic component is of limited significance. Monozygotic twin pairs with one schizophrenic proband show only about 40% concordance, thus leaving the responsibility for the greater part of the aetiology to environmental factors. Unfortunately, our ignorance about relevant environmental factors is nearly complete. Our knowledge that phenocopies of schizophrenia of organic origin do exist does not help us very much. We know that brain disease like Huntington's chorea, encephalitis and others can give rise to conditions which symptomatically cannot be distinguished from the other schizophrenias, and that similar conditions can be caused by drugs like amphetamine and related compounds. But such organically caused schizophrenic pictures account for less than 10% of all schizophrenic psychoses. The rest is silence.

On the other hand, the fact that schizophrenic states can be caused by well known organic factors may lead some to believe that all schizophrenias are the result of organic processes which, however, unfortunately cannot be revealed with current techniques. But that is in any case a matter of faith and should not induce us to close our eyes to the possibility of a predominantly psychological aetiology of some cases of schizophrenia.

The search for causative environmental factors is very intensive, both in the laboratories and using sociological techniques. For the latter, it would be of great importance if it could be demonstrated that the incidence of schizophrenia differs in different environments. In that case, research could be directed towards other, possibly relevant, differences between the various environments. Here, psychiatric epidemiology comes into the picture. Disappointingly, it must be said that the search for such variations of the incidence of schizophrenia in different populations, or in the same population at different points of time, has failed to give any remarkable results, except in the case of limited population groups living in isolates where arbitrary accumulations of schizophrenia, or absence of that disease, can of course easily occur. Thus, in an isolated North Swedish population, Böök (1953) found a disease expectancy of schizophrenia of close to 3%, in contrast to figures of between 0.7 and 1.0% normally found when larger populations are studied. Also, the incidence figures for schizophrenia found during a multinational WHO study (1986) in a number of countries in different parts of the world are strikingly similar.

The abundant literature concerning the frequency of schizophrenia may give a confusing impression. The widespread interest in epidemiological studies has induced many research workers, who are not sufficiently familiar with epidemiological techniques, to publish observations and conclusions which were naive and misleading, and which nevertheless occasionally had great public impact because they tallied with popular prejudice or ideologically based wishful thinking. In some cases it was obvious that even research workers, who in other contexts merited respect, were ignorant of the differences between basic epidemiological concepts like prevalence, incidence and morbid risk, carelessly comparing figures from incidence studies with figures from prevalence studies etc., in spite of the fact that these figures are of course incommensurable. It is also amazing that many comparative studies have been published in which factors like differences in age distribution and mortality have not been taken into consideration, likewise such important factors as internal migration within a population. It is comforting that many widespread ill-founded epidemiological conclusions have been corrected in recent years by competent epidemiologists, not least from Great Britain. The Maudsley Lecture by Edward Hare (1983) is a good example of this trend.

The use of the three concepts—prevalence, incidence and morbid risk, respectively—each has its indications and, under favourable research conditions, it is also possible to convert one to the other. Whereas prevalence figures are especially useful for determination of the needs for treatment and social assistance to sick people, incidence figures are those which are most readily applicable for aetiological studies. Their main weakness is that they are often derived from hospital statistics, which not only cover just a fraction of cases, but are also hampered by the fact that the extent of this fraction may differ enormously between different populations. Here nosocomial factors and threshold factors are of decisive importance, varying as they are with the social and economic conditions of the population, with the distance to the hospital, with the reputation of the hospital, with the demographic characteristics of the population, urban or rural, etc. It is therefore essential that studies of incidence and prevalence which are based on contacts with the health system, especially hospitals, are supplemented by field studies which determine true incidences and prevalences. But field studies require much manpower and time and can therefore be applied to only relatively small populations. The ideal is to combine studies based on contacts with the health system with field studies, the aim of the latter first of all being to serve as correctives to the former.

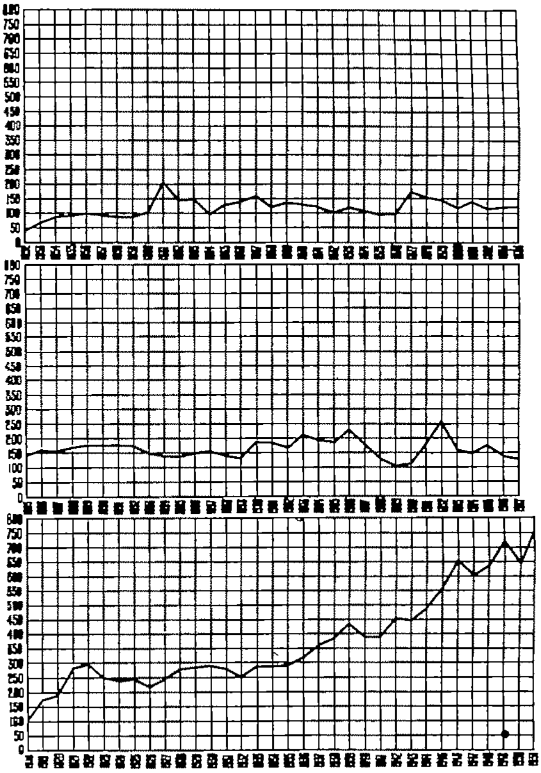

FIG 1. Annual admissions to the Aarhus Psychiatric Hospital 1852–1952.

Can we use hospital statistics at all for the determination of incidence of schizophrenia? In general, it can be said that admission statistics give only vague and unreliable estimates of the true incidence. Even in a relatively homogeneous, small population like the Danish, the probability of being admitted to a psychiatric ward varies markedly between different parts of the country. For instance, different investigations during the last decades have shown that this probability has been five to eight times greater in the city of Copenhagen than in rural areas, although the differences with regard to incidence of mental disorders could not be nearly as great. In addition, within the metropolitan area, the admission rate is much larger in the poorer parts of the city than in the more wealthy parts. However, closer analysis reveals that, with regard to schizophrenia and other severe psychoses, these differences are not nearly as large, the differences in admission rates thus being mainly due to short-lasting reactions, mostly of non-psychotic nature.

Where differences over time are concerned, it is striking that changes in admission rates are correlated primarily to availability of space in the psychiatric institutions. This is illustrated in Fig. 1, which shows admissions to the Psychiatric Hospital in Aarhus during the first 100 years of its existence, from 1852 to 1952. When the hospital was opened, it had only 130 beds. During the first years there were of course many admissions, but just until the hospital was full. The admission rate then decreased until 1861 when a large extension of the hospital took place. In 1864 there was again a short decrease; in that year Denmark was at war with Germany, and patients avoided admission to hospital, if ever possible. The stagnation during the 1870s was interrupted by the opening of a new hospital in the same area in 1877. The increase after the turn of the century was caused by transfer of chronic patients to two nursing homes. After 1910 there was also an increase caused by the introduction of supervised family care to which many of the chronic patients were transferred, and this permitted admission of more fresh cases. During World War I, there was the usual reluctance to be admitted to hospital. There was a special reason for the steep rise after the war: malaria therapy was introduced, and this very specialised treatment was concentrated in two Danish hospitals, one of them being the Aarhus hospital. This implied that patients with GPI were sent to Aarhus from a number of other hospitals and sent back again after treatment, thus accelerating the turnover in Aarhus. After the introduction of shock therapy in the 1930s, there was a new rise, with an interruption at the beginning of World War II. In conclusion, it can be said that there is no reason to suppose that any of the big changes in admission rates were caused by changes in the incidences of mental disorders; if anything, the changes rather reflected the natural history of hospital building and, more or less, the political history of Denmark.

With regard to the evaluation of admission statistics, it is generally agreed that *first admissions* are by far the most interesting. They must be related much more closely to the incidences than the total number of admissions could ever be. But closer scrutiny reveals that 'first admission' is a concept which is less useful than it might appear at first sight. The first condition is naturally that 'first admission' should mean 'first ever admission to a psychiatric institution'. In countries with national psychiatric registers, 'first admission' in this more narrow sense is a reasonably meaningful concept. But only with a number of reservations.

Serious difficulties arise, for example, when mental disorders are classified according to systems, in which the *disease course* plays a role for definition of classes. If there is a class for recurrent depressions, no first admission is possible, because a patient must have been admitted previously to fall into this class. Current classifications of bipolar illness present similar difficulties and, all in all, it cannot be recommended that definitions of classes include criteria dealing with disease course.

Schizophrenia presents special difficulties. Firstly, there is usually an interval between the onset of the disorder and the first admission, often of several years' duration. Some schizophrenics are never admitted, in some cases because they die before admission would have taken place. Secondly, many schizophrenics are not given the diagnosis of schizophrenia during their first hospital admission. At the Institute of Psychiatric Demography in Aarhus, which takes care of the Danish National Psychiatric Register, Munk-Jørgensen (1985) has recently studied a cohort of all Danish patients first admitted during 1972 who had received the diagnosis of schizophrenia either during that year or some time during the following 10 years. The study showed that only 50% of the male and 40% of the female patients were diagnosed as suffering from schizophrenia during the first admission; the remaining patients were given the diagnosis during later admissions. On the average, 1.7 years for men and 2.2 years for women elapsed between the patient's first contact with an inpatient institution and the diagnosing of schizophrenia. In retrospect, most of the patients later diagnosed as schizophrenic suffered from the same disease during their first admission and could as well have received the diagnosis at that time; reluctance to use a prognostically serious label presumably caused a delay in many cases. Therefore, although these patients were in reality schizophrenics on first being admitted, they would not be recognised as such by official statistics, and they would never appear as 'first admissions for schizophrenia'.

The ideal will be to compensate for these errors by performing field studies with the aim of finding patients who were never admitted, and to determine the age of onset for these patients as well as for those who have been admitted. But such studies are only possible under special, very fortunate circumstances. It is therefore important that Ødegaard (1952) in Norway has devised methods which make it possible to calculate, on the basis of hospital statistics and case histories, the number of schizophrenics not yet admitted under the assumption—which seemed to be valid in Norway—that sooner or later all schizophrenics who survive will be admitted. Compensation should then, if possible, also be made for the deficit caused by the fact that some schizophrenics may die at a stage when they are psychotic, but without definite schizophrenic symptoms.

In spite of all these sources of error and the uncertainty of the results of the admission statistics, it is of interest to study recent results from centres in which admission statistics can be assumed to be relatively complete and reliable. A recent report by Eagles & Whalley (1985) is highly relevant in this respect. They studied first admissions to Scottish psychiatric hospitals during the period 1969–1978. Age-standardised rates for schizophrenia fell from 19.6 per 100 000 population to 11.8, a drop of 40%. The rates for affective psychoses also decreased, but only by 28%. Other changes were not significant. These results are important because they come from an area in which registration seems to have been excellent for a long time.

In Denmark, nationwide psychiatric registration was started in 1938 and became relatively complete in 1952. Since 1970 the data have been computerised (Dupont, 1983). Thus, although some of the technical conditions are adequate, the interpretation of results to be mentioned should be made with some reserve. The presentation has a mainly methodological scope, even though some of the results may be interesting enough to stimulate further and more penetrating research.

First, mention will be made of results from some systematic census studies which have been performed since 1942, with 5-year intervals (Weeke *et al*, 1986). All patients resident in psychiatric institutions in Denmark were registered on particular census days in September in each of the census years. The data were arranged according to age, sex, institutions and, since 1957, diagnosis. As expected, there were significant changes during all quinquennia. It was interesting that, with regard to age and sex distribution, linear extrapolations from 1942 to 1957 predicted with great accuracy the status in 1970; however, after this year the figures developed in a way which had not been predicted. Most notably, predicted increases of the oldest age groups did not occur. With regard to diagnostic distribution, the most remarkable feature was the decrease of resident schizophrenics since 1953. It had been anticipated that there would be a considerable decrease, but it was a surprise to see that this decrease was much more pronounced in the females, than in the males, and particularly among middle-aged schizophrenic females. Modern combined drug and social therapy seems to work much better in females than in males. The decrease in the prevalence of resident schizophrenics which was so spectacular until 1970 has continued since then, but at a more moderate rate.

But what about the admission rates? During the last 15 years, there have been about 40 000 admissions annually to Danish psychiatric institutions. However, the percentage of first admissions has decreased slowly, from 36 to 26%. An increasing proportion of the admissions concerns day-patients.

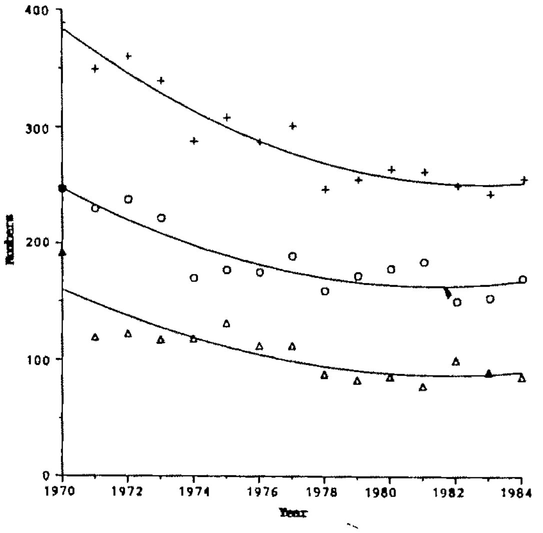

Fig. 2. First admission of schizophrenics 1970–1984 (0 male, Δ female, + male and female).

A special study has been performed concerning first admissions for schizophrenia during the period 1970–1984. Figure 2 shows the absolute numbers of first admissions for both sexes combined. The decrease is remarkable. However, it seems that the decrease is slowing down during the last few years. It might be expected that the decrease would be expressed more for females, but that is not the case. The cause for the previously mentioned difference between the sexes with respect to prevalence of resident schizophrenics is obviously *not* that schizophrenia is becoming less frequent in females than in males, but rather that female schizophrenics stay for a shorter time in hospital and have better chances to stay out of hospital after discharge.

How can we interpret the decrease of first admissions of schizophrenics? In view of the serious sources of errors, all interpretations should be made with the greatest caution. The simplest explanation for the decrease might be that psychiatrists are becoming increasingly reluctant to make the diagnosis of schizophrenia unless the evidence practically forces them to do so; an increasing number of schizophrenics would then never appear as first admissions. Others may, during the first undiagnosed admissions, be treated so successfully that they can be cared for on an outpatient basis in the future. If eventually the diagnosis of schizophrenia is made, it will not appear in the admission statistics.

Some further circumstances will have to be taken into consideration. During the observation period, have there been other notable changes in the admission patterns in general? Although the total number of admissions has not changed significantly, the rate of first admissions, as mentioned, has decreased moderately, from 36 to 26%. In contrast, for schizophrenia the relation between first and later admissions has changed drastically, from 11% in 1970 to 4% in 1984, the change being caused both by a decrease in first admissions as well as by an increase in all admissions, the latter being much more marked than the very moderate increase in all admissions for all diagnoses. These facts indicate that during this period the trend has been to substitute a number of long-lasting admissions by a greater number of short admissions; if the first admissions also tend to be shorter, the likelihood of reaching a diagnosis of schizophrenia at this point of time will decrease.

An attempt to control for all these sources of error would be very laborious. It is therefore tempting to try to attack the problem from a different angle. In this connection, it seems appropriate to mention a study which is currently being performed on the Danish island of Bornholm. I shall first present a short orientation concerning some psychiatric epidemiological investigations in this population.

During the 1930s, I was engaged in epidemiological studies on Bornholm. One of my aims was to try to ascertain all cases of psychoses that had occurred on the island since 1892, and, in addition, I made a special census of psychoses on a particular date in 1935. After finishing the study, I published a monograph (Strömgren, 1938) and concluded the book with a paragraph emphasising the importance of performing repeated surveys. I stressed how useful it would have been if somebody had carried out a similar census 50 years earlier. Then 2 years ago I was approached by four young psychiatrists who worked in the psychiatric department of the general hospital on Bornholm. They had noted the concluding paragraph in my book and pointed out that, now 50 years had nearly elapsed, it was time to repeat the survey. I agreed wholeheartedly, and during these 2 years I have been in cooperation with the Bornholm psychiatrists, first of all with Dr Søren Bøjholm.

One of the first aims has been to perform a census of schizophrenia for a particular date in 1983 and to compare this with the census from 1935. One advantage would be that the principal investigator was the same, and that the diagnostic evaluations may therefore be reasonably comparable. Another advantage is that conditions on Bornholm make epidemiological studies relatively easy. The population has not changed very much over the 50 years. All the time the population has been about 50 000, but of course the age distribution has changed. The main occupations are still fishing and farming. Industry has increased but does not dominate.

The technique for information collection differed between the two census studies. In the 1930s, I worked at the local general hospital and examined all the case notes since 1892, and in addition I used all the case notes concerning people from Bornholm who had been admitted to psychiatric hospitals in Denmark since 1859. All general practitioners on the island were visited, and in each parish there were key people who knew everybody in that parish. From these sources, information was collected about all people who were regarded as being mentally deviant. Most of them I saw personally. With regard to schizophrenia, I think I have reason to believe that very few cases may have escaped me, if any.

Since the 1930s, many things of relevance have happened, first of all a psychiatric department was established in 1961 in the general hospital in the city of Rønne. The files of this department were therefore the starting point for the new census. In addition, the general practitioners were questioned and the National Psychiatric Register was consulted.

During the recent census there were some problems which did not exist in the 1930s. First of all, complications arose when schizophrenia-like psychoses co-existed with drug abuse. In these cases, it could be very difficult to ascertain which came first, the psychosis or the abuse. Next there were some of these very patients who lived on Bornholm, but could not be regarded as belonging to the population there. They came from other parts of the country and had been drug abusers for some time when they decided, occasionally in groups, to go to Bornholm to stay in the nice countryside there, maybe in a deserted farm house. In such cases, as in other cases in which mental abnormality is the real cause for transfer to Bornholm, the person should not be regarded as belonging to the Bornholmian population. Thus, if a young schizophrenic living in Copenhagen feels persecuted and believes he will be safer in his parents' summer cottage in Bornholm and therefore moves over and stays, he does not belong to the population there. On the other hand, if people who are Bornholmians move to other parts of the country, as a consequence of their schizophrenia, they should still be regarded as belonging to the Bornholmian population. Such demographic criteria are occasionally as difficult to ascertain as the diagnosis of schizophrenia.

Difficulties were also presented by a few people who for several years have been living in complete isolation and refuse contact. It will nevertheless usually be possible to reach a probable diagnosis, and

TABLE I
Prevalence of schizophrenia on Bornholm in 1935 and in 1983

	Numbers					
	Males		*Females*		*M+F*	
Age	*1935*	*1983*	*1935*	*1983*	*1935*	*1983*
15–24	4	3	1	1	5	4
25–34	12	21	9	2	21	23
35–44	16	6	16	8	32	14
45–54	14	14	13	6	27	20
55–64	5	4	11	13	16	17
65–74	4	7	13	9	17	16
75–84	0	5	5	5	5	10
85+	0	1	0	5	0	6
Total	55	61	68	49	123	110

in any case there are so few of these cases that they cannot affect the statistics seriously.

The result of the two censuses can be seen in Table I. It is remarkable that, while the prevalence of schizophrenia in males has not changed significantly, there is a decrease with regard to female schizophrenics. The figures should be taken with considerable reserve. The study has not been completed, there are some loose ends, but it seems unlikely that the final result will deviate very much from the one seen in the table. Table II shows rates.

Here again, we seem to be confronted with a notable difference between the sexes with regard to schizophrenia. These differences might possibly provide a clue to factors of importance for the development of schizophrenia. Why is it that while maturation in general occurs earlier in women than in men, onset of schizophrenia occurs definitely later in women? A number of investigations on large representative samples of schizophrenics show this difference. Figure 3 shows the distribution of age at onset of schizophrenia in males and females based on a large amount of material from Munich to which I had access 50 years ago (Strömgren, 1935). Later studies have given curves of quite similar shape. This difference in the age of onset is much more difficult to explain than the fact that schizophrenic women are becoming much less frequent in hospital treatment than are schizophrenic males. But even the sex difference found in the census investigation in Bornholm can have a rather trivial explanation. Schizophrenia in females, arising later than in males, will relatively often lead to a mainly paranoid state with relatively good preservation of the personality which at that stage is already mature and fully developed. It may then be difficult to make the diagnosis of schizophrenia at once; but in any case these patients are treated, quite often with good results, bringing them into a state which never becomes definitely schizophrenic. If this is the explanation, it is gratifying for the patients but a disappointment for the scientist, because this explanation will not give any information concerning the aetiology of schizophrenia.

TABLE II
Prevalence of schizophrenia on Bornholm in 1935 and in 1983

	Rates					
	Males		*Females*		*M+F*	
Age	*1935*	*1983*	*1935*	*1983*	*1935*	*1983*

Total	0.37	0.32	0.41	0.25	0.39	0.29

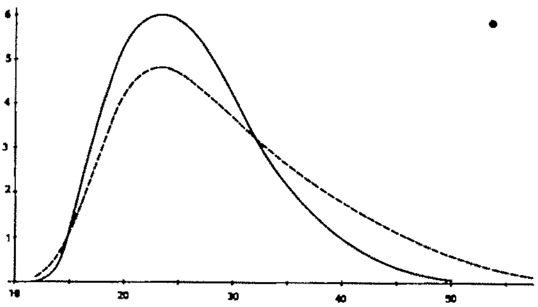

FIG. 3. Age of onset in schizophrenia (——males, - - -females).

A further step in the investigation could then be to try to identify patients who could fit this pattern, i.e. patients who have come to treatment in a stage which *may* be an early stage of schizophrenia, who have received adequate antipsychotic treatment with considerable effect and are now in a stage which cannot be diagnosed as schizophrenia. If the number of such cases should correspond to the number of schizophrenic females which seem to be 'missing' in the census, this might be taken as tentative support for the explanation given for the unexpected decrease in the number of female schizophrenics. It may seem to be quite utopian to find all such cases. In most populations, it would no doubt be unrealistic, but conditions for investigations of this kind are fortunate in the Bornholm population which is remarkably well served in a psychiatric respect, and in which identification of ill people is feasible to a degree that is unusual for a population of that size.

At this point, it may be relevant to mention another study which was carried out on Bornholm in the 1930s (Strömgren, 1937). At that time, I found the study to be of little interest, but it does touch on problems which in recent years have come into focus in schizophrenia research. At that time the Bureau of Hygiene of the League of Nations was interested in possible relationships between infectious diseases and mental disorders. Being supposed to have information on most cases of mental disorder that had occurred on Bornholm during the recent decades, I was asked to investigate whether any correlations between incidences of infectious diseases and mental disorders respectively could be ascertained. I therefore arranged the cases of major mental disorders known to me according to year of onset and compared this distribution with data collected by the medical officers of health who had continuously received information from the general practitioners about infectious diseases of public interest. No correlations whatever could be found between occurrence of epidemics of such diseases and onset of mental disorders. Many possibilities for different lengths of periods of latency between infections and occurrence of the different mental disorders were examined, but the results were entirely negative. Needless to say, these findings cannot in any way disprove the possibility that there may be correlations between particular, perhaps unreported, infectious diseases and occurrence of schizophrenia.

One of the aims of my lecture has been to illustrate ways in which large-scale statistics of a nationwide nature and more intensive studies of limited population groups may supplement each other, and also in which ways census studies and longitudinal studies can be brought into meaningful connection with each other. However, it must be admitted that even under favourable circumstances, the conclusions that can be drawn from such combined investigations are mostly uncertain and will have to be assessed with great caution. Nevertheless, it is my feeling that epidemiological studies may stand just as good a chance of providing clues to the aetiology of schizophrenia as do other scientific approaches being pursued at present. This is my excuse for discussing, in considerable detail, mainly methodological problems in psychiatric epidemiology.

Review Article

Biological and Neuropsychological Approaches to Childhood Autism

MARGOT R. PRIOR

There is growing conviction that childhood autism is a biologically based disorder. The evidence that has accrued in a variety of areas pertaining to biological abnormality in autism suggests that, with the possible exception of genetic factors, very few data are available that illuminate the autistic disorder specifically. Neurological models which might be useful in guiding further research are discussed and reasons for the slow progress in this important aspect of the study of autism are identified.

Early childhood autism, which traditionally has been considered to be the earliest form of childhood psychosis, has been the subject of a quantity of research greatly out of proportion to its incidence in the population. It is a severe disorder, beginning probably from birth, characterised by major deficits in cognitive and social functioning. In its purest form, autism occurs in less than two children in 10 000 (Lotter, 1966); in its more diluted form, i.e. when diagnostic criteria are less stringent, the incidence is still only about four in 10 000. Its interest to clinicians, researchers and lay people alike is perhaps due to the very mysteriousness of the condition, the fact that most of the children given this diagnosis tend to be attractive and appealing in appearance without outward physical signs of the very serious handicap it entails, and the fact that it is a disorder which is manifest from a very early age.

Early infantile autism was first delineated by Kanner in the early 1940s and is characterised by the following symptoms: extreme aloneness or self-isolation and withdrawal from social contact from very early in development, an obsessive need for sameness in the environment and in daily routine, a preoccupation with objects which are often used in peculiar non-functional ways, ritualistic and stereotyped behaviours such as rocking, spinning or manipulation of objects, extreme resistance to new learning, severe language disability which for more than half of cases means muteness and in most of those who do speak, bizarre non-functional language including echolalia, perseverative and stereotyped speech, idiosyncratic use of pronouns and sometimes metaphorical language.

The use of gestures to communicate, and symbolic play are notably absent in infancy (Ricks & Wing, 1976; Prior, 1979). Although Kanner claimed in his original formulations that these children had 'good cognitive potential', it has now been demonstrated repeatedly that most autistic children are moderately or severely retarded and that only a small minority (about one-fifth) show evidence of normal intellectual ability, albeit of a rather uneven and idiosyncratic kind. Autistic children with measured IQs below 40 or 50 have a very poor prognosis (DeMyer *et al*, 1973). Data on intellectual functioning levels together with results of many experimental studies suggest that the disorder is primarily cognitive rather than emotional and consequently the direction of basic research has been adapted to this conceptualisation of the disorder (Rutter, 1983).

In the most recent DSM-III classification of disorders of childhood and adolescence (American Psychiatric Association, 1980), infantile autism is now categorised as a 'pervasive developmental disorder'. This reclassification of autism involves a shift from a perception of the disorder as a psychosis to a perception of a disorder which involves failure to follow the normal developmental process in social, cognitive and psychological spheres.

Psychodynamic aetiology was stressed by Kanner and other early workers, although paradoxically at the same time it was asserted that the disorder was 'inborn' (Kanner, 1943, 1944). On the basis of his observations of the parents of autistic children, Kanner believed that they were 'refrigerator'-type parents—cold, intellectual, obsessive, highly educated people who had been unable to form the normal bonds of attachment with their child. Happily, little credence is given now to this proposition. A number of studies have supported the counter claim, that where it is found that a majority of parents of autistic children are intelligent and highly educated (and this has indeed been the case in a number of studies [e.g. Lotter, 1966; Prior *et al*, 1976]), this has most likely been the result of referral artefacts (Schopler *et al*, 1979; Wing, 1980).

The current consensus of opinion is very much towards a biological basis for childhood autism (Rutter, 1974; Schopler, 1983). However, very much more progress has been made in describing and measuring the behavioural deficits in the disorder than in solving the puzzle of its aetiology. In this paper, research aimed at revealing biologically based abnormalities in autism will be reviewed briefly as a preface to a discussion of current neuropsychological models which might be helpful in guiding future research of an aetiological type.

Biological factors

Because of the rarity of the syndrome, genetic studies are necessarily scant. However, there is accumulating evidence of some kind of genetic influence, albeit of a non-specific kind. The rate of autism and of milder cognitive and language disorders in siblings of autistic children is notably in excess of population-based rates (Lotter, 1966; Spence, 1976; Folstein & Rutter, 1977; August *et al*, 1981; Minton *et al*, 1982).

Ritvo and his colleagues (1982, 1985) have mounted a major study of genetic influences in autism and are investigating families with more than one autistic child in the USA, Canada and France. Although they report that their data are consistent with autosomal recessive inheritance of the disorder, it may not be possible to generalise the results from these very unusual families. In fact, the nature of inheritance is unknown at this stage and only a general influence can be identified. The raised risk of perinatal stress, especially in twin studies, dilutes the force of the genetic hypothesis (Folstein & Rutter, 1977). Furthermore, the well documented excess of males with the disorder has not been explained by any of the genetic theories.

A number of studies have reported significantly more perinatal complications in children who developed autism and childhood psychosis (Kolvin *et al*, 1971; Harper & Williams, 1975; Prior *et al*, 1976; Finegan & Quarrington, 1979; Links *et al*, 1980; Tsai & Stewart, 1983). However, without detailed and accurate records of pregnancy and birth histories, we are hampered by reliance on retrospective reporting by parents which may be particularly suspect when reasons for the severe abnormalities of autism are being sought. Gillberg & Gillberg (1983) have circumvented this problem in their report of a Swedish population study based on extensive and systematic official birth history data. They found high scores for 'reduced optimality' (i.e. pre-, post- and neonatal factors which are related to risk) in their sample of autistic children, thus supporting some influence of birth risk factors in at least a proportion of cases.

Major areas of research effort in the search for physiological abnormalities in autism have been neurobiological investigations and EEG, sleep, and evoked potential studies. These areas are replete with methodological difficulties. Despite this the importance of neurobiological factors in the aetiology of autism is argued strongly. Although earlier it was held that autistic children were free from overt signs of brain damage (indeed, in the past this has been one of the exclusionary criteria for the diagnosis of autism), more recent research concerned with neurobiological factors has supported biologically based aetiology. Kolvin *et al* (1971) and Lobascher *et al* (1970) concluded that at least half of their cases showed organic signs, whilst DeMyer *et al* (1972) found that only 14% of their autistic sample were within normal limits on brain dysfunction indices.

Motor milestones are often reported as slow (Kolvin *et al*, 1971; Ornitz *et al*, 1978; DeMyer *et al*, 1981), and DeMyer (1976) has claimed that gross motor abilities involving the lower limbs are at a retarded level although less handicapped than fine motor and ball-handling skill. She sees autistic children as a neurologically disabled group and has described them as 'dyspraxic' (see also Jones & Prior, 1985).

Delayed development of hand preference in autistic children is of a similar order to that reported for retarded children (Colby & Parkinson, 1977) and this has been interpreted as suggestive of neurobiological dysfunction or delay (but see McCann, 1981). Lower levels of functioning have been found in autistic children with mixed handedness compared with those with established dominance (Tsai, 1983; Fein *et al*, 1984*b*). A review of 13 studies of handedness by Fein *et al* (1984*a*) showed only two with a real increase in left-handedness, although overall they concluded that left-handedness was about twice as common as in a normal population and almost exactly the same as in retarded and epileptic populations (Satz, 1973). A proportion of neurodevelopmental findings are undoubtedly the result of inclusion of children with a variety of biologically based disorders in which autism is part of the symptoms; nevertheless there does seem good evidence to support the significance of abnormalities in this area. Damasio & Maurer (1978) have emphasised the motor deficits of autistic children and suggested that, in particular, they may implicate basal ganglia structures in the aetiology.

The incidence of reported EEG abnormalities in autistic children ranges from 10 to 83% with an average of 52% (DeMyer *et al*, 1981). However, there are no EEG abnormalities which are unique to the disorder and there is minimal evidence concerning localisation of any EEG abnormalities; most commonly they are distributed diffusely (Waldo *et al*, 1978). Tsai *et al* (1981) have reported a significantly greater incidence of epilepsy and abnormal EEGs in autistic girls as compared with autistic boys, attesting to the greater severity of the disorder in females. Unsurprisingly, cases with normal EEG are likely to have a better long-term outcome (Tsai *et al*, 1985). However, on the basis of a thorough review of psychophysiology in 'early onset psychosis', James & Barry (1980) could only conclude that "characteristic spontaneous EEG irregularities, indicating some CNS disability *may* exist". The question of interpretation of abnormalities as indicating under- or over-arousal remained unresolved according to their review, although maturational factors were seen as influential. Evidence related to cardiovascular, respiratory and electrodermal activity was similarly inconsistent and inconclusive. Sleep studies (e.g. Ornitz *et al*, 1969; Tanguay, 1977) suggest immaturity in REM sleep but no unique abnormality.

Brainstem dysfunction in autistic children has been explored using brainstem auditory evoked potentials (BAEPs) (Skoff *et al*, 1980; Fein *et al*, 1981; Gillberg *et al*, 1983a). Longer brainstem transmission time and a suggestion of greater abnormalities on the left side of the brain are reported. However, a significant proportion of cases show no abnormalities at all, and some studies do not find prolonged transmission times (Courchesne *et al*, 1984).

A number of researchers have postulated specific brainstem abnormalities as basic to autism. These include Rimland (1964), who suggested the reticular formation, Ornitz (1978), who suggested the vestibular system, MacCulloch & Williams (1971), a dorsal brainstem lesion around the nucleus of the tractus solitarius, Simon (1975), a specific lesion in the inferior colliculi, and Rosenblum *et al* (1980), "neurological dysfunction in the auditory system at the brainstem level". Empirical data to support these hypotheses have not been forthcoming. Tanguay *et al* (1982) have proposed a relationship between abnormal auditory evoked responses, implicating auditory processing deficits in some children, and the maldevelopment of neural substrates at critical early periods. This suggestion is supported by the conclusions of Niwa *et al* (1983) who investigated the P300 component of evoked response potentials in a pitch-discrimination task in autistic subjects. However, the influence of attention deficits and/or auditory processing problems on findings in this area has been investigated insufficiently to allow anything but speculation at this stage.

Biochemical research was reviewed by Piggott in 1979 and found to offer equivocal and inconsistent findings. Variation in biochemical research techniques, lack of normative and developmental data (Ritvo, 1979) and the uncertain influence of mental retardation on reported data contribute to this unsatisfactory state of affairs. There has been much focus on serotonin function areas in the central nervous system because of the theory that abnormalities of serotonin metabolism are related to psychotic disorders (e.g. Ritvo *et al*, 1970; Piggott *et al*, 1975; Yuwiler *et al*, 1975). Hyperserotoninaemia has been reported in approximately one-third of autistic children but is similarly found in many medical and neuropsychiatric disorders and in mental retardation. Its relationship to central nervous system functioning, or to any symptom or behaviour is uncertain (Kuperman *et al*, 1985). DeMyer *et al* (1981) have concluded that 'blood serotonin levels are more strongly related to intellectual status than to psychiatric diagnosis'. Neuroendoncrinological studies (Yamazaki *et al*, 1975), immunological studies (Stubbs, 1976; Stubbs *et al*, 1977) and enzyme studies (e.g. Jackson & Garrod, 1978) have also produced some evidence for non-specific abnormalities but no coherent pattern related to a diagnosis of autism has emerged. Gillberg's group reported inferential evidence for the importance of abnormalities of monoamine metabolism in at least some autistic children (Gillberg *et al*, 1983*b*).

Wing's claim (1981) that autism is not a single disorder but occurs in combination with many other developmental and organic disorders is consistent with the evidence noted above, i.e. many physiological and biochemical disturbances seen in some autistic children are also seen in children with a wide range of disturbed functioning.

Autism Association with other Disorders

It appears that one of the possible causes of autism may be a viral infection either early in life, or, as an effect later in development of a 'slow virus'. The incidence of autism in rubella children is much in excess of that in the normal population (412 in 10 000 *vs* 2–4 cases per 10 000) (Chess, 1971, 1977) suggesting a specific link between the rubella virus and the development of autism. Chess (1971) has suggested that autism may be one consequence of the invasion of the central nervous system by the rubella virus in the same way as autistic behavioural disturbance can be produced by viral encephalitis. However, any form of brain damage such as that produced by the rubella virus, may increase the risk of the development of behavioural and cognitive handicaps such as those found in autism.

Autism or autistic behaviour is also associated with some other organically based disorders involving retardation, most strongly with tuberous sclerosis, phenylketonuria and encephalitis. It has also been associated with coeliac disease, congenital syphilis, histidinaemia, toxoplasmosis, purine disorder, infantile spasms, Cornelia de Lange syndrome, congenital cytomegalovirus (Stubbs *et al*, 1984), neurofibromatosis (Gillberg & Forsell, 1984) and the fragile X syndrome (Meryash *et al*, 1982; August & Lockhart, 1984). However, the association may be between retardation and autism rather than any relationship with specific syndromes. Study of the symptoms associated with these disorders serves to illustrate the fact that autistic behaviour can be a consequence of various kinds of insults to the nervous system as well as developing without apparent organic origin.

Consideration of these kinds of data suggests a somewhat perturbing trend in biological research in autism. In the eagerness to discover biological markers, a wide variety of cases whose *primary diagnosis* is not autism but who have autistic behaviour is being investigated. Whilst this shows clearly that autistic symptoms may be correlates of numerous biologically based disorders, it does not contribute to our understanding of the basis for autism in the original Kannerian sense of the syndrome. It is important to focus research efforts on the children with no other obvious disorders if we are to contribute to knowledge of aetiological significance in autism. Thus, out of a multitude of studies, little has emerged to illuminate the puzzle of the aetiology of autism. Of the areas considered, genetics seems to offer the most promise for productive further exploration. However, the development of some theoretical underpinning to guide further research may be essential if wasteful 'fishing expeditions' are to be avoided. One approach to such an effort is to take a neuropsychological view of the handicaps of autism and to consider whether this has any advantages in guiding further research.

Neuropsychological approaches

There have been some attempts in recent speculations concerning the causes of autism to formulate some neurological models which can subsume findings in the area so far. For example, an early study by Hauser *et al* (1975) using pneumoencephalography showed enlargement in the ventricular system in a proportion of a sample of autistic children. They suggested a deficiency of substance in the left hemisphere of the brain. Unfortunately their group was a heterogeneous one precluding conclusions specific to autism.

DeLong (1978) concedes that autism probably has multiple aetiologies but suggests that at least for a subgroup a neuropsychological interpretation is relevant. He draws attention to the similarities between symptoms in autism and in the Kluver-Bucy syndrome. This disorder occurs in man as a consequence of bilateral surgical ablations of medial temporal lobes or following herpes simplex encephalitis. "Deficits in the Kluver-Bucy syndrome have been described as an incapacity for adaptive social behaviour, and a loss of recognition of the significance of persons and events. Such patients show an empty blandness, an absence of emotion or concern for family or other persons, and pursue no sustained purpose in activity" (DeLong, 1978). This description does suggest a strong parallel with the most severe and more retarded cases of autism but is less generally apt for the higher functioning group. In addition, autistic children do sometimes show extreme concern for particular (idiosyncratic) events or activities and, at least in middle childhood, for particular people, i.e. empty blandness does not characterise their behaviour in situations important to them, and this may be observed even in the most severe cases.

DeLong also comments on some similarities between autistic behaviour and some features of Korsakoff's psychosis; however, the work of Boucher & Warrington (1976) which was concerned with this issue did not provide convincing evidence for relating the amnesic syndrome to autism. Drawing on the neurological data relating to Korsakoff's psychosis, DeLong (1978) suggested that a left unilateral medial temporal lesion, which impairs verbal learning, and an intact right hemisphere might produce the pattern (which is seen in autism) of adequate learning of places, faces and nonsense patterns together with impaired social interaction and language. The problem of lack of transfer of damaged left hemisphere function to the intact right hemisphere (which would normally be expected in lesions sustained early in life) is accounted for by suggesting that such transfer only occurs when the lesion involves specific left hemisphere cortical areas. DeLong has suggested, as have Prior and her colleagues (Prior, 1979; Hoffman & Prior, 1982), that for the majority of severely retarded cases, where intellectual and social functioning is extremely impaired, damage would have to be bilateral with no right hemisphere compensation or normal development. The idea of unilateral and bilateral damage in accounting for the considerable differences between high and low functioning cases is attractive; however, the clinical picture is not sufficiently clear cut, nor are the neuropsychological data yet compelling enough to consider this idea more than an hypothesis worthy of further investigation. Furthermore, comparisons between ablated monkeys, Kluver-Bucy syndrome adults, alcohol-induced brain damage and a developmental disorder like autism must be considered as tenuous to say the least.

These hypotheses have been evaluated further by Hetzler & Griffin (1981) who have suggested bilateral neuropathology of the temporal lobes of the brain as a significant aetiological factor in autism. Their model is based not only on the Kluver–Bucy amnesic syndrome data but also incorporates evidence relating to developmental dysphasia and Geschwind's (1965) 'disconnection syndrome', as well as a variety of reported organic factors. However, these authors concede the difficulties involved in developing this proposition. Such a model would not account satisfactorily for the high functioning autistic sub-group.

Neurological models

A speculative neurological model for autism was elucidated by Damasio & Maurer in 1978. Beginning with the observation that the abnormal behaviour in autism is comparable to that seen in brain damaged adults, especially those with frontal lobe, basal ganglia or limbic system damage, they propose that "autism is consequent to dysfunction in a complex of bilateral CNS structures that include mesial frontal lobes, mesial temporal lobes, basal ganglia . . . and thalami . . ." (1978). As evidence for this theory they cite the motility disturbances, abnormalities of muscular tone, posture, gait and akinesia as signs of dysfunction of the basal ganglia, especially the neostriatum and of closely related structures of the medial aspects of the frontal lobes (see also Tsai *et al*, 1981). This also fits with the disturbances of communication, attention and perception which can occur as a result of mesial frontal lobe lesions and basal ganglia abnormalities and which are characteristic of autism. The ritualistic and compulsive behaviours commonly observed in autism are also seen in patients with damaged frontal lobes, especially those with early sustained lesions. The inability to learn by experience, to adapt to changing environments and to organise appropriate responses are common to both autistic and frontal lobe patients. Perseverance, lack of initiative, concreteness, shallow affect and lack of empathy similarly can be observed in individuals with autism and damage to the frontal lobe. Hoffmann & Prior (1986) have attempted to explore this hypothesis by administering tests purported to be sensitive to frontal lobe dysfunctioning. Autistic children did indeed show deficits in behaviour mediated by the frontal lobe, e.g. on the Milner Maze Test, where their performance was characterised by inability to form plans or strategies, considerable perseverance, inability to profit from feedback concerning errors and lack of affective response to either correct or incorrect choices. Their performance on the Wisconsin Card Sorting Test suggested impaired conceptualisation abilities, and again perseverance reponses were common.

Whilst these hypotheses deserve further investigation, the leap from behavioural observation to physiological abnormality is large and in view of the lack of evidence for lesions in autistic patients the proposed connection between frontal lobe damage and autistic behaviour remains tenuous. It would be encouraging if there were some evidence of structural abnormalities consistent with neuropsychological hypotheses. However, recent computerised axial tomography studies (Hier *et al*, 1979; Damasio *et al*, 1980; Campbell *et al*, 1982; Gillberg & Svendsen, 1983; Prior *et al*, 1984) have offered little support. Although abnormalities are sometimes reported in a proportion of samples, they seem to be characteristic of those children with severe retardation and other organic signs and thus say little specifically about autism. No abnormalities have been observed in high functioning cases (Prior *et al*, 1984). Of course the problem may be biochemical rather than structural, but again there is no evidence to support any hypothesised abnormality.

The speculative nature of these neurological models is well illustrated by the fact that, whilst using the same kind of behavioural evidence, Damasio & Maurer (1978) implicate older cortical structures, whilst Tanguay (1977) suggested the neocortex as the locus of abnormality. Tanguay's suggestion is that autism may be the result of dysfunction in the "frontolimbic system" and that autistic behaviour may be a later reaction to a major early insult. He emphasised the importance of timing in the effects of any neural insult—a theoretically critical issue which can only be investigated properly with comprehensive developmental research (Tanguay & Edwards, 1982). Geschwind & Galaburda (1985) have speculated recently on cerebral lateralisation, biological mechanisms and pathology of various kinds, including developmental disorders such as autism. Whilst their arguments are too complex to be summarised here, the nub of their thesis in relation to autism concerns links between anomalies of handedness, differential rates of development of the right and left cerebral hemispheres and aspects of the immune system. An interesting suggestion is that the worsening of conditions at or near puberty (as, for example, the increase in fits seen in autism) argues for a major role for the sex hormones. They also suggest that the higher incidence of developmental learning disorders (of which autism might be an extreme form) in males may be related to testosterone possibly interacting with genetic influences.

A limbic system model proposed by Lamondella in 1977 has received surprisingly little attention in the autism literature. Lamondella suggests that the limbic system may be the site of dysfunction in autism. This suggestion had in fact been made in 1960 by Schain & Yannet and a related hypothesis had been proposed again in modified form by Deslauriers & Carlson in 1969. Since the limbic system is responsible for arousal, social interaction, emotion, sensory thresholds, attention to novel stimuli, as well as basic communication functions, Lamondella (1977) suggests "intrinsically or extrinsically triggered limbic malfunctions as the cause of early infantile autism". Limbic epilepsy may also be proposed as the cause of the increase in fits in adolescent and young adult autistic cases. Derryberry & Rothbart (1983) have noted that the limbic system seems to be significant in controlling information processing within the cortex via the reticular system and that "direct cortical projections from the limbic systems may serve to alert central processing mechanisms to the presence of a motivationally-relevant stimulus, and to direct attention toward that stimulus".

Lamondella offers a model which divides the limbic system into subsystems that correspond to levels of forebrain organisation all of which are relevant to communicative functions. Level 1 involves primary sign behaviour, Level 2 visceral sign complexes, Level 3 somatic sign schemata and somatovisceral sign learning, Level 4 signal communication, and Level 5 propositional communication. It is hypothesised that in autism there is a breakdown around Level 4 (thalamic level) or in some cases even lower in the system. The thalamus is said to be influential in neocortical speech systems and thus this is relevant to the fact that a universal symptom in autism is language abnormality (Prior *et al*, 1976). Such a model also fits well with Hermelin's (1982) conceptualisation of autism as a failure to develop adequate communication in either thought *or* feeling as a consequence of developmental deficits in genetically preprogrammed capacities for non-verbal as well as verbal communication. The interesting question of critical periods for the development of limbic functions is also pertinent since it brings in the notion of the ability to compensate for damaged limbic components. This factor is unknown in human subjects but data from monkeys suggest that compensation is only possible up to the age of 1 or 2 years. After that time limbic damage has permanent effects on behaviour. Given the belief that autism is supposed to have its onset before the age of 2 or 3 years, it is of interest to speculate on the relationship between age of onset and plasticity in the limbic system. It is claimed that other structures may take over limbic system functions in congenital damage cases.

Although Lamondella's model is difficult to test and lacks support from any extant physiological or neurological studies, it appears worthy of further exploration since it fits well with behavioural observations of autistic children, it incorporates the notions of critical periods and plasticity, it covers the most critical and basic aspects of autism, the social, motivational and communication deficits, and it is not weakened by the findings so far of no particular structural defects in the brains of autistic individuals. It also allows for some heterogeneity in symptoms and could conceivably be elaborated to include some explanation of the fact that a proportion of autistic children do show normal intelligence, can develop language and can make a reasonable adjustment in later life. However, imperfect understanding of the structures and the functions of the limbic system, its relationship with other brain functions and the connexion between structure and function in the individual almost certainly means that we may wait some time before being able to explore this hypothesis productively.

At a somewhat different level of brain organisation are the proposals of Prior and Hoffmann (Prior, 1979, 1984; Hoffmann & Prior, 1982). Drawing together behavioural, psychometric, neurophysiological and experimental evidence, they have suggested that it appears that much of the behaviour of higher functioning autistic children, at least, reflects mediation or control of function by the right hemisphere of the brain. Hoffmann & Prior (1982) have presented evidence which shows that higher functioning autistic children perform according to their chronological age level on tests purporting to assess right brain functions but are grossly handicapped, in fact perform more poorly than mental age-matched (and therefore younger) controls, on tests purporting to assess left brain functions. In addition, there is some evidence from dichotic listening studies (Prior & Bradshaw, 1975) and from evoked potential data suggesting abnormal lateralisation of function (Dawson *et al*, 1982, 1986). It is not yet clear whether this pattern of performance in autistic children reflects immaturity (with right hemisphere and less mature strategies being used in all cognitively demanding situations) or whether there is in fact selective damage to the left hemisphere in a subgroup of autistic children who may have been able to compensate for such damage by greater development of the right hemisphere permitting the attainment of quasi-normal intelligence except on tests of high language content.

There are a number of theoretical problems with this model, especially since, if autism has its onset early in life, there ought to be more effective compensation for lateralised damage in the infant brain. Bilateral damage would have to be proposed for the low functioning majority of autistic children who share many of the behavioural symptoms while lacking the intellectual and language attainments of the high functioning group. If it were considered that the two groups represent different disorders, of course this problem would be resolved in part at least. Reference to Kanner's early discussions of the disorder suggest that early cases of infantile autism did not show the degree of global retardation which characterises so many of the cases now called autistic. Despite these caveats, there is some further support for the proposals in a study of lower functioning autistic children using the Halstead–Reitan Neuropsychological Test Battery for Children (Dawson, 1983), where results essentially similar to those of Hoffmann & Prior (1982) were found with significantly greater left than right hemisphere dysfunction. However, Dawson was careful to note that only five autistic children showed left hemisphere impairment alone, while the remaining five showed involvement of both hemispheres. Failure to develop the usual symbolic functions of the left hemisphere, in particular language and gesture, is hardly surprising since autistic children appear to be detached from normal social, cognitive and linguistic experiences during the early developmental period. Thus, atypical hemisphere functioning is perhaps to be expected.

Lamondella has suggested that the two hemispheres may process limbic input differentially. This allows some connecting threads to be drawn between his model and the hemispheric dysfunction proposals. Lamondella notes support for the hypothesis of differential interaction of right and left hemispheres with limbic functions and suggests that integration of the two functional areas may occur via systems which could in turn be part of the limbic system. Further exploration of such a hypothesis may well be very profitable. Fein *et al* (1984*a*) have been critical of the hypothesis of left hemisphere dysfunction on the grounds that it lacks corroborative anatomical and physiological data, and are sceptical regarding its applicability to low functioning cases and the perceived overemphasis of the language disorder in autism with de-emphasis of the social impairments. They also note the marked individual differences across cases and the likelihood of similar variation in the biological/neural substrates of the disorder. However, this does not mean that investigations permitted by more sophisticated techniques of measurement of brain function at various levels will not prove illuminating on this proposal.

It is also helpful to consider Luria's (1973) model of brain function, which is based on the idea of three zones—primary, secondary and tertiary—each zone being dependent on adequate development of the preceding structures and functions. Abnormality in the primary functional area leading to inadequacy in processing of sensory information will in turn affect higher cortical processes. The development and interaction of these zones in young children is seen as a 'bottom-upwards' process, with intact lower zones necessary for adequately functioning higher zones—the secondary and tertiary areas. Thus multiple impairments in a number of areas can occur as a consequence of insult or deficits in a single primary area. This principle of hierarchial development of the brain could then explain the varying consequences of early damage to the limbic system (see also Tanguay & Edwards, 1982).

Conclusions

Consideration of the research concerned with biological factors in childhood autism shows that we appear to have made little progress in the search for specific aetiologies. It seems that we may not be very much closer to finding causes than we were 40 years ago when the search began. There are some obvious reasons for this lack of progress despite considerable quantities of research. In summary, they are:

(a) the use of heterogeneous samples of autistic children who, whilst they all exhibit autistic behaviour, do so for many different and sometimes obvious reasons;
(b) methodological and measurement problems in biological research which makes findings difficult to replicate and to interpret;
(c) lack of normative developmental data in most of the areas studied making comparisons between autistic and other groups difficult to interpret;
(d) failure to take account of retardation factors in sample selection and measurement;
(e) the primitive nature of our knowledge of brain physiology and of the functional relationships between brain and behaviour.

It certainly appears at this stage that a search for a unique cause for autism may be fruitless. A variety of neuropathological conditions may produce broadly defined behaviour symptoms. Wing (1981) and others argue strongly, and many researchers who work with autistic children imply, that autism may not be a specific disorder but can occur in many very different types of children with many different underlying problems. If the search for aetiological factors in childhood autism is to be more productive in future, it will be necessary to focus on 'pure' cases (as far as this is possible), who are preferably high functioning, thus minimising the influence of retardation. Equally important is hypothesis-testing on the basis of theoretical models that could account for the core features of the disorder and that arise from, and are consistent with, current neuropsychological data.

A Self-rating Scale for Bulimia
The 'BITE'

M. HENDERSON and C. P. L. FREEMAN

A new brief questionnaire, the Bulimic Investigatory Test, Edinburgh (BITE), for the detection and description of binge-eating is described. Data from two separate populations demonstrate satisfactory reliability and validity. The scale has measures of both symptoms and severity. All items in the DSM-III definition of bulimia and Russell's definition of bulimia nervosa are covered but the questionnaire is more than just an operationalised checklist of these diagnostic criteria.

Over the past few years, there has been increasing interest in the prevalence of binge-eating (bulimia nervosa). One study (Halmi *et al*, 1981) found a prevalence rate of 13% in a population of American college students. In order to identify binge-eaters the authors used a short questionnaire, which included items on all the DSM-III (American Psychiatric Association, 1980) criteria for bulimia and for bulimia nervosa as described by Russell (1979).

A more recent study by Pyle *et al* (1983) used a slightly more sophisticated questionnaire to look at the incidence of binge-eating among college freshmen. This study found a prevalence of 4.5% in women, which is substantially lower than the figures found by Halmi *et al* (1981). This questionnaire also used DSM-III criteria, with the inclusion of questions about behaviour in the past as well as at the time of completion. In addition, Pyle *et al* defined what they meant by the term 'binge-eating', something that Halmi *et al* did not.

Hawkins & Clements (1980) have produced a questionnaire designed to provide descriptive and quantifiable information about behaviour and attitudes in binge-eating. This is a small 19-item questionnaire, of which only nine items are used in the calculation of the score. Although it could be used as a method of quantifying binge-eating behaviour, it is not comprehensive enough for epidemiological work. Nor would it be sensitive enough to enable identification of those with less severe pathology.

Much descriptive work has been completed on bulimia nervosa (e.g. Russell, 1979; Palmer, 1979; Wardle & Beinhart, 1981; Fairburn, 1983). It would seem more appropriate, when designing a questionnaire concerned with a particular disorder, to incorporate all the currently acknowledged symptoms and behaviour associated with that disorder. However, all the previous studies have relied on the American DSM-III diagnostic criteria and have used these as a basis for the wording of the individual items. Often no attempt is made to define what is meant by such terms as 'binge-eat'. Such questionnaires were all designed for the individual studies of which these were part and were often not tested for reliability or validity on separate populations before use. In a comprehensive review of the available questionnaires for use with binge-eaters, Gandour (1984) concludes that those currently available have been little used and they lack data on their reliability and validity. However, she indicates that a reliable self-report instrument would have a number of important potential uses.

These methods of questionnaire design are likely to lead to an overestimate of the incidence rate through misinterpretation of the questions, and/or a loss of information about those suffering from a less severely disordered eating pattern. The present authors felt that there was a need for a more sensitive questionnaire that would allow such people to be identified. In addition, there was a need for a tried and tested tool that explored fully the symptoms and behaviour associated with bulimia nervosa.

A questionnaire of this type has been developed for anorexia nervosa by Garner & Garfinkel (1979), the Eating Attitudes Test (EAT). The EAT has been used successfully as a screening tool to identify both clinical (Garner & Garfinkel, 1979) and subclinical cases of anorexia nervosa (Button & Whitehouse, 1981). Although the EAT is a proven, reliable questionnaire, it was not designed for use with binge-eaters: the questions are specifically concerned with the behaviour and feelings associated with anorexia nervosa. A more

comprehensive measure of eating behaviour is the Eating Disorders Inventory (EDI) Garner *et al*, 1983*a*). This is a questionnaire designed to assess a broad range of attitudes and behavioural aspects of anorexia nervosa and bulimia. It consists of eight subscales measuring dimensions such as drive for thinness, body dissatisfaction, bulimia and maturity fears. This instrument is a major advance in the comprehensive assessment of anorexia nervosa. However, it was not designed for use with binge-eaters. The population on which it was validated consisted of 129 anorexic subjects and did not include a group of binge-eaters that met DSM-III criteria. Furthermore, it is too cumbersome for use as a quick screening instrument.

Although binge-eaters share some common features with anorexics, they differ in many ways (Russell, 1979). Binge-eating is a very secret behaviour, and it is helpful to subjects completing a questionnaire if they can see that the questions are relevant to their problem.

In summary, the aim of the present study was to design and validate a questionnaire which would identify binge-eaters, provide clinical information on cognitive and behavioural aspects of the disorder and have properties similar to those of the EAT. The questionnaire was to include the most pertinent signs and symptoms associated with binge-eating described currently in the literature. This could then be used both as an epidemiological tool for identifying cases and subclinical cases in a given population and as a screening device for use in outpatient clinics. In addition, it would serve as a useful tool in a treatment setting, allowing severity to be quantified as well as being a measure of the response to treatment.

Method

Questionnaire design

An initial list of all the symptoms and behaviour associated with binge-eating was compiled from the current literature. In particular, those symptoms described by Palmer (1979), Russell (1979) and Bruch (1975) were included, as well as those listed in DSM-III. From these symptoms a preliminary list of questions was devised, which was given to a group of subjects, both normal controls ($n=10$) and binge-eaters ($n=7$). The binge-eaters were all currently receiving treatment from one of the authors.

After discussion with the subjects, all those items that were either misinterpreted or found to be ambiguous were deleted or reworded. A final list of 40 questions was then drawn up, the Bulimic Investigatory Test, Edinburgh (BITE). This list contained seven items concerned with dieting behaviour, 27 concerned with symptoms and behaviour associated with binge-eating and six concerned with more specific information on the frequency of the most significant behaviour.

For the pilot studies, a further section of questions intended to elicit information about eating patterns and demographic factors, e.g. height, was included in the BITE.

Pilot studies

Two independent groups of binge-eaters and normal controls were used to test the validity of the BITE. An important test of the cross-validity of a questionnaire is its ability to predict a case when it is applied to a new group not involved in its original preparation. Accordingly, two separate studies were undertaken. The first study was designed to test the face validity of the questionnaire and its acceptability to subjects. Following statistical analysis, the results from this study were used to decide which items should be included in the final form. The second study was designed to test the validity of the BITE as a sensitive and reliable measure of binge-eating, and its ability to identify cases accurately. Scoring was designed to be carried out by computer, using the SPSS system (Nie *et al*, 1975). However, scoring by hand can also be done quickly and easily.

First study subjects

For the first study the subjects were 15 female binge-eaters (Binge 1) and 40 normal controls (Control 1) (13 males, 27 females). The binge-eaters were all at various stages of treatment by one of the authors. The control group included various members of the hospital staff and a group of third-year medical students.

First study results

The BITE was given to both groups of subjects and then scored. On the basis of the scores on the 27 questions on symptoms, the subjects were divided into two groups, high scorers (total score >20) and low scorers (total score <20). Sixteen subjects were high scorers (mean score $=33.73$, s.d. $=8.14$) and 39 low scorers (mean score $=5.9$, s.d. $=5.37$).

The high-scoring group contained 14 subjects from the Binge 1 group and two from the Control 1 group. In the low-scoring group there were 38 from the Control 1 group and one from the Binge 1 group. It seemed clear that the questionnaire had succeeded in identifying the bulimic cases. Statistical analysis confirmed that this result was highly significant ($\chi^2=95.69$, $P<0.00001$, 1 d.f.). The one bulimic patient who scored below 20 was at the end of treatment.

The individual items in the BITE were then analysed to determine whether they were significant determinants of group membership, again using the chi-squared test. All but three of the items concerning symptoms were significant at the level $P<0.05$ (1 d.f.), while 19 were significant at a level of $P<0.0001$. On the basis of this analysis, it was decided to include three items from the dieting questions in the calculation of the total score. The three non-significant items were retained as it was felt they provided important clinical information.

Following the results of the first study, we subdivided the questionnaire into two subscales. The first subscale is

TABLE I
Comparison of subjects and controls for the first and second studies

Group	*n*	*Age (years, mean ± s.d.)*	*Height (cm, mean ± s.d.)*	*Weight (kg, mean ± s.d.)*
Binge 1	15	24.3±5.7	163.3±6.2	59.5±11.7
Control 1	40	24.2±5.5	168.2±9.9	61.3±9.8
Binge 2	32	25.3±6.0	163.5±3.4	62.1±10.1
Control 2	32	24.8±5.0	165.2±7.3	57.4±5.8

made up of 30 items relating to symptoms, behaviour and dieting, and is called the Symptom Subscale. The second subscale contains the six items measuring the severity of behaviour as defined by its frequency, and is called the Severity Scale.

The Symptom Subscale has a maximum possible value of 30, with a score of 20 as the criterion score. The Severity Subscale has a maximum score of 39 and a score of five or above is considered to be clinically significant. A total combined score of 25 or above is considered to be indicative of the presence of a severely disordered eating pattern.

Second study subjects

The subjects were 32 female binge-eaters (Binge 2), each of whom fulfilled DSM-III criteria for bulimia. These women took part in the study before commencing treatment. The control group (Control 2) comprised 32 normal females, including members of the hospital staff and psychology students. Demographic data on the subjects from both studies are presented in Table I.

Second study results

The BITE was completed by the second group of binge-eaters and normal controls. None of the normal control group produced a Symptom Score (mean = 2.94, s.d. = 2.94) or a Severity Score (mean = 0.44, s.d. = 0.29) above the cut-off points (20 and 5 respectively). All the binge-eaters scored above the cut-off on the Symptom Subscale (mean = 26.03, s.d. = 2.25), (see Fig. 1). All the binge-eaters scored above the cut-off score of 25 for the total score (mean = 36.19, s.d. = 4.47). Two subjects had a Severity Score of 4, the rest scored 5 or above (mean = 10.16, s.d. = 3.63). A total of 20 (62.5%) of the control subjects scored a Severity Score of 0. There is a highly significant difference between the total scores of the two groups ($t = 31.68$, $P < 0.001$, 62 d.f.) and also between both the Symptom Subscale and the Severity Subscale scores ($t = 35.29$, $P < 0.05$, 62 d.f. and $t = 14.65$, $P < 0.05$, 62 d.f. respectively).

Reliability

The inter-item reliability coefficient for all items on each subscale was calculated using the α reliability coefficient. Using both the subjects and the controls from the second study, α was 0.96157 for the Symptom Subscale and 0.62342 for the Severity Subscale. Thus, the items in both subscales demonstrate a high degree of internal consistency.

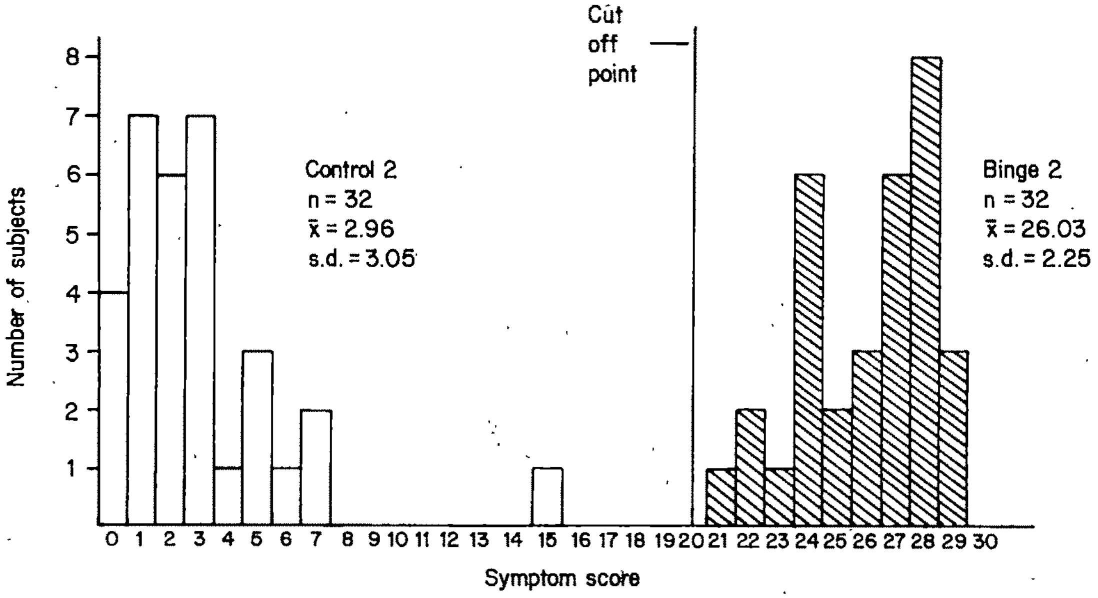

FIG. 1 This figure shows the scores of the Control 2 and Binge 2 subjects on the Symptom Subscale.

TABLE II
Correlation between BITE and EDI, EAT scores

Measure correlated with BITE		*Pearson's correlation coefficient* *R*	*No. of subjects* *N*	*Significance* *P<*
EDI	Drive to thinness	0.589	57	0.001
	Binge-eating	0.678	57	0.001
	Body dissatisfaction	0.352	57	0.01
	Ineffectiveness	0.506	57	0.001
	Perfectionism	0.143	57	NS
	Interpersonal distrust	0.227	57	NS
	Interoceptive awareness	0.519	57	0.001
	Maturity fears	0.438	57	0.001
EAT	Total	0.697	72	0.0001
	Diet subscale	0.621	72	0.0001
	Binge subscale	0.681	72	0.0001
	Oral control	0.232	72	NS

Relationship between the BITE and other measures

Scores on the BITE from the second group of binge-eating subjects (Binge 2) were compared with their scores on the EAT and the EDI (Garner & Garfinkel, 1982). The mean scores for the Binge 2 subjects on the EAT was 43.5 and the mean score on the bulimia subscale of the EDI was 10.5. The correlations are shown in Table II.

Third study subjects

Twenty-seven subjects in a treatment study completed the BITE before treatment, 8 weeks into treatment and at the end of 15 weeks treatment, to assess whether the questionnaire was sensitive to change. These subjects were all female, all met DSM-III criteria for bulimia and were bingeing at the rate of at least four times per month at the start of the study. The mean rate of bingeing was 7.2 times per week, at the start of the treatment study. The age-range of these subjects was 16–42 years, with a mean age of 22 years. The study involved a comparison of behaviour therapy, cognitive therapy and group psychotherapy. The preliminary results have been reported elsewhere (Freeman *et al*, 1985).

Third study results

Table III shows the scores on the BITE for these 27 subjects before starting treatment for bulimia, after 8 weeks and at the end of therapy. Significant reduction in scores occurred between 0–8 weeks and 8–15 weeks, showing that the BITE is highly sensitive to change.

TABLE III
Change of BITE scores with treatment

	n	*Mean*	*s.d.*	*t value*	*2-tail P*
Pre-treatment	27	33.85	5.97		
				8.24	0.000
Mid-treatment	27	15.03	8.60		
				3.78	0.001
End-treatment	27	8.29	6.02		

Fourth study subjects (test–retest reliability)

To assess test–retest reliability, 30 non-case female controls completed the BITE on two occasions separated by at least 1 week. These subjects were members of hospital paramedical staff and mothers whose children attended a university day nursery. In addition, ten women who were DSM-III bulimia cases completed the BITE on two occasions separated by 15 weeks. These were subjects who were part of a waiting-list control group for another study. All ten subjects met DSM-III criteria at the end of the waiting-list period as well as at the beginning.

Fourth study results (test–re-test reliability)

Mean scores for the 30 non-case women who completed the BITE on two occasions were as follows: first occasion 3.33 (s.d. 2.57, range 0–9), second occasion 3.22 (s.d. 2.27, range 0–9). A Pearson coefficient of $R = 0.86$ ($P < 0.0001$) shows a high positive correlation between the two sets of scores. Mean scores for the ten bulimic women who completed the BITE on two occasions were as follows: first occasion 34.4 (s.d. 3.13, range 29–38), second occasion 31.8 (s.d. 5.39, range 21–42). A Pearson coefficient of $R = 0.6825$ ($P < 0.05$) shows a high positive correlation.

Discussion

It is important that a questionnaire of this type should be easy to administer, acceptable to subjects and simple to score. The BITE meets all these requirements. It is self-explanatory and can easily

P 25 420

be given to large numbers of subjects for completion. Those subjects who have significant scores can be identified easily. The average time for completion of the questionnaire is less than 10 min. Those subjects who took part in the pilot studies reported that the BITE was very acceptable and many commented on the pertinence of the questions.

The sensitivity of any new screening instrument is very important. The results clearly indicate that the modified BITE produces neither false positives nor false negatives. It is able to distinguish binge-eaters clearly from normal subjects while at the same time picking up less severe levels of pathology.

As can be seen in Fig. 1, one subject from the Control 2 group had a Symptom Score of 15. This score would suggest that the subject had a disturbed, but not clinically significant eating pattern. This subject was interviewed and it became clear that she had unusual eating habits, but not of sufficient severity to be classified as a binge-eater. Similarly, two of the Control 1 subjects were found to have disordered eating patterns, again not clinically significant. The presence of subjects with eating problems in groups of randomly selected controls illustrates the problem of finding 'normal' control subjects. Binge-eating is not a discrete clinical state; there are many intermediate subclinical stages between normality and a DSM-III diagnosis of bulimia nervosa. A shorter questionnaire relying on a few key questions is unlikely to have been sensitive enough to identify and classify correctly such subclinical cases.

Furthermore, the BITE would appear to be sensitive to changes in both symptoms and behaviour during and after treatment. In this capacity it should serve an invaluable role as a measure of response to treatment and allow comparison of the effectiveness of different treatment methods.

Unlike other questionnaires used to identify binge-eaters, the BITE does not differentiate subjects in an all-or-none fashion. There is a large range of possible scores, and subjects suffering from binge-eating of various degrees of severity can be detected. Those scoring less than the criterion score of 25, but more than a proposed lower cut-off of 10, are likely to reflect a subclinical group of subjects who have a disordered eating pattern.

The use of frequency of behaviour as a measure of severity is open to criticism. However, the authors feel that it will serve as an alerting sign to those using the questionnaire. A high score on this scale (10 or above) indicates that the subject is binge-eating and fasting or engaged in purging behaviours more than once a week. It is acknowledged that frequency of behaviour alone does not automatically imply a case. A possible diagnosis of binge-eating should only be made when the subject scores above 25 on the two scales combined. There are groups of patients, e.g. psychogenic vomiters, as described by Fairburn (1979), who may well score highly on the question concerning self-induced vomiting, but who would not meet the criteria for a diagnosis of binge-eating.

The BITE is put forward as a tested, valid questionnaire, designed specifically for use by those interested in binge-eating. There is a need for such an instrument for use in the field of eating disorders, which will allow workers to look at binge-eating in a systematic way. The EAT has been used widely. However, it is of limited use when looking at the symptoms of binge-eating. It is hoped that the introduction of the BITE will provide as useful a measure of binge-eating tendencies as does the EAT of anorexia nervosa.

The significant positive correlation between the EAT and BITE scores for the Binge 2 subjects does not mean that the two questionnaires are measuring the same clinical dimension. Both instruments are measures of abnormal eating patterns and attitudes to eating, but the behaviour with which each is concerned differs significantly. It would not be possible to assign a DSM-III diagnosis of bulimia to a subject on the basis of their score from the EAT. The BITE provides such information as well as detailed clinical information concerning a subject's individual difficulties. In addition, it allows the clinician a method of quantifying the severity of the problem as defined by frequency of behaviour and the presence or absence of different purging behaviours.

Until now, all those concerned with eating disorders have had to design their own questionnaires. These are often not tested for reliability and validity on a separate population before use. The BITE is put forward as a tried and tested alternative that can be used easily for a range of different purposes. It can be used in epidemiological studies concerned with incidence rates in various populations; it can also be used as a measure of severity of symptoms and response to treatment by both psychiatrists and GP's in outpatient work. Its ease of administration and scoring makes it ideally suited to these tasks.

There is still a great deal of ignorance concerning both the incidence and prevalence rates of binge-eating. Fairburn (1983) states that bulimia nervosa may well be an important undetected source of psychiatric morbidity. The BITE should go some way to help us gain a better understanding of the true prevalance rate of binge-eating.

Appendix 1

BITE instructions for administration and scoring

Uses

The BITE is a 33-item self-report measure, designed to identify subjects with symptoms of bulimia or binge-eating. It can be used to identify binge-eaters in a given population or as a screening instrument for use in a clinical setting. In addition, it serves as a useful measure of severity and response to treatment. The BITE consists of two subscales: the Symptom Scale, which measures the degree of symptoms present, and the Severity Scale, which provides an index of the severity of bingeing and purging behaviour as defined by their frequency. Scores on the Symptom Scale can be subdivided into three groups: high, medium and low scores. Those subjects achieving a high score have a high probability of meeting the DSM-III criteria for bulimia and Russell's (1979) criteria for bulimia nervosa. An additional front data sheet accompanies the BITE, which provides useful demographic data relevant to the study and treatment of binge-eating. Use of this data sheet is optional; it does not contribute to the subject's final score.

Administration

When the BITE is used as a screening instrument or in survey work, the subjects should be asked to complete the questionnaire based on their feelings and behaviour over the past 3 months. Where the BITE is to be used as a measure of response to treatment, only the past month should be considered.

Scoring

Symptom Scale

All the questions, with the exception of the three starred (6, 7 and 27), make up the Symptom Scale. The underlined questions (1, 13, 21, 23, and 31) score one point for a 'No' response. The remaining 25 items score one point for a 'Yes' response. The maximum possible score is 30.

Severity Scale

The three starred items (6, 7 and 27) comprise the Severity Scale. The total score is the sum of the numbers corresponding to the circled responses.

Interpretation of results

Symptom Scale

In general the scorers on this scale can be subdivided into three main groups; high scorers with a score of 20 or more, medium scorers with a score of 10–19 and low scorers with a score below 10.

A symptom score of 20 or more indicates a highly disordered eating pattern and the presence of binge-eating. There is a high probability that a subject who achieves such a score will fulfil DSM-III criteria for a diagnosis of bulimia.

A symptom score in the medium range (10–19) suggests an unusual eating pattern, but not to the extent that a subject in this range would meet all the criteria for a diagnosis of bulimia. An example of this might be a compulsive eater who eats excessively but does not binge-eat. A score in the 15–19 range should certainly be followed up by an interview. Subjects in this category may well reflect a subclinical group of binge-eaters, either in the initial stages of the disorder or recovered bulimics.

A symptom score in the low range (0–10) falls within normal limits. Such a score indicates the absence of both compulsive eating and binge-eating.

Severity Scale

The severity scale measures the severity of bingeing and purging behaviour, as defined by its frequency. A score of 5 or more on this scale is considered clinically significant. A score of 10 or more indicates a high degree of severity. A significant score on this scale should ideally be followed up by interview, regardless of the symptom score.

A high score on this scale alone may identify the presence of psychogenic vomiting, or laxative abuse, in the absence of binge-eating.

Any score on the severity scale should be checked against the relevant question in order to check for this type of behaviour.

Appendix 2

Bulimic Investigatory Test, Edinburgh (BITE)

Optional front data sheet

1. What is your sex? MALE 1 FEMALE 2 (*please circle number*)

2. Are you:
MARRIED 1 SINGLE 2 DIVORCED 3 SEPARATED 4 WIDOWED 5

3. What is your occupation? ______________

4. If married, what is your spouse's occupation? ______

5. What is your age? ________years

6. What is your height? ______feet ______inches, or ______cm

7. What is your weight? ______stone ______pounds, or ______kg

8. What is the most that you have ever weighed? ______stone ______pounds, or ______kg

9. What is the least that you have weighed at your present height? ______stone ______pounds, or ______kg

10. What would your ideal weight be if you could choose it? ______stone ______pounds, or ______kg

11. Do you feel yourself to be VERY OVERWEIGHT 5
OVERWEIGHT 4 (*please*
AVERAGE 3 *circle*
UNDERWEIGHT 2 *number)*
VERY UNDERWEIGHT 1

12. Do you have regular periods? (if applicable) YES 1 NO 2

13. How often, on average, do you eat the following meals?

	EVERY-DAY	5/7 DAYS	3/7 DAYS	1/7 DAYS	NEVER	
BREAKFAST	1	2	3	4	5	
LUNCH	1	2	3	4	5	(*circle*
DINNER	1	2	3	4	5	*number*)
BETWEEN MEAL SNACKS	1	2	3	4	5	

14. Have you ever consulted someone in a professional capacity for advice on dieting/eating? YES 1 NO 2

15. Have you ever been a member of a slimming club? YES 1 NO 1

16. Have you ever suffered from any type of eating disorder? YES 1 NO 2

. . . . . if yes, please give details over:

Bulimic Investigatory Test, Edinburgh

1. Do you have a regular daily eating pattern? YES NO

2. Are you a strict dieter? YES NO

3. Do you feel a failure if you break your diet once? YES NO

4. Do you count the calories of everything you eat, even when not on a diet? YES NO

5. Do you ever fast for a whole day? YES NO

*6. . . . If yes, how often is this?
EVERY SECOND DAY 5 2–3 TIMES A WEEK 4
ONCE A WEEK 3 NOW AND THEN 2 HAVE ONCE 1

*7. Do you do any of the following to help you lose weight? (*circle number*)

	Never	Occasionally	Once a Week	2–3 Times Week	Daily	2–3 Times a Day	5+ Times a Day
TAKE DIET PILLS	0	2	3	4	5	6	7
TAKE DIURETICS	0	2	3	4	5	6	7
TAKE LAXATIVES	0	2	3	4	5	6	7
MAKE YOURSELF VOMIT	0	2	3	4	5	6	7

8. Does your pattern of eating severely disrupt your life? YES NO

9. Would you say that food dominated your life? YES NO

10. Do you ever eat and eat until you are stopped by physical discomfort? YES NO

11. Are there times when all you can think about is food? YES NO

12. Do you eat sensibly in front of others and make up in private? YES NO

13. Can you always stop eating when you want to? YES NO

14. Do you ever experience *overpowering* urges to eat and eat and eat? YES NO

15. When you are feeling anxious do you tend to eat a lot? YES NO

16. Does the thought of becoming fat *terrify* you? YES NO

17. Do you ever eat large amounts of food rapidly (not a meal)? YES NO

18. Are you ashamed of your eating habits? YES NO

19. Do you worry that you have no control over how much you eat? YES NO

20. Do you turn to food for comfort? YES NO

21. Are you able to leave food on the plate at the end of a meal? YES NO

22. Do you deceive other people about how much you eat? YES NO

23. Does how hungry you feel determine how much you eat? YES NO

24. Do you ever binge on large amounts of food? YES NO

25. . . . If yes, do such binges leave you feeling miserable? YES NO

26. If you do binge, is this only when you are alone? YES NO

*27. If you do binge, how often is this?
HARDLY EVER 1 ONCE A MONTH 2
ONCE A WEEK 3 2–3 TIMES A WEEK 4
DAILY 5 2–3 TIMES A DAY 6

28. Would you go to great lengths to satisfy an urge to binge? YES NO

29. If you overeat do you feel *very* guilty? YES NO

30. Do you ever eat in secret? YES NO

31. Are your eating habits what you would consider to be normal? YES NO

32. Would you consider yourself to be a compulsive eater? YES NO

33. Does your weight fluctuate by more than 5 pounds in a week? YES NO

British Journal of Psychiatry (1987), **150**, 25–29

Physical and Psychological Characteristics of Five Male Bulimics

J. DUNKELD TURNBULL, C. P. L. FREEMAN, F. BARRY and A. ANNANDALE

The case histories of five men who met DSM-III criteria for bulimia and details of their physical characteristics are given. Various eating disorder questionnaires were administered and the results indicated that most of these instruments would not have identified the men as suffering from an eating disorder. The necessity of caution in asserting the prevalence of bulimia using these measures is emphasised.

Bulimia as defined by DSM-III (American Psychiatric Association, 1980) is an eating disorder characterised by recurrent episodes of binge-eating which leave the patient feeling depressed and guilty. There is an awareness that the eating pattern is not normal and a fear of being unable to control the amount ingested. To avoid putting on weight, the patient will resort to inducing vomiting, abusing laxatives or diuretics, severely restrictive diets, or a combination of these methods.

The prevalence of bulimia in males has been estimated at between 0.4 and 5% of the US college population (Halmi *et al*, 1981; Pyle *et al*, 1983). In the UK, most estimates of bulimia in males are extremely small; Freeman & Henderson (1986) found one male bulimic in a survey of 625 male students; Clarke & Palmer (1983) found none in a postal survey of 120 male students. The prevalence of bulimia in women is much greater. Estimates of the incidence in US populations vary from 2.1 to 13% (Halmi *et al*, 1981; Pyle *et al*, 1983). Surveys in the UK have found the prevalence of women meeting DSM-III criteria for bulimia in certain populations to be between 1.9 and 4.5% (Cooper & Fairburn, 1983; Freeman & Henderson, 1986). As Fairburn (1984) has pointed out, the majority of these estimates are derived from the evidence of self-report questionnaires given to highly selected populations, usually of students. There is no reason to suppose that students are particularly disposed to eating disorders; in fact the most recent survey, of consecutive patients in a family practice, found that 23% of the women and 10% of the men had abnormal eating habits and concerns, as assessed by their replies to questions about binge-eating, vomiting etc. At least 10.9% met the criteria for bulimia (Zinkand *et al*, 1984). In addition, such self-report questionnaires have been derived from information on and validated for groups of women; there is no reason to suppose bulimic men would necessarily produce high scores.

Published reports of bulimia in men are rare, although anecdotal evidence abounds. Some physical and sexual data on 14 male bulimics has been provided by Herzog *et al* (1984), and Gwirtsman *et al* (1984) reported some clinical data and neuroendocrine findings for three male bulimics.

Button & Whitehouse (1981) used the EAT scale derived by Garner & Garfinkel (1979) to try to identify individuals with abnormal concerns with eating and weight. Using a cut-off point of 30 on this scale they found no men with problems. None of the 120 male students surveyed by Clarke & Palmer (1983) scored above 30 on the EAT scale and were therefore excluded from further study.

In this paper we report the case histories of five men who met DSM-III criteria for bulimia. Their scores on various questionnaires, including the EAT, are compared with available norms.

Subjects

Four of the men were referred by their GPs to a treatment study of bulimia. The first case was identified during the student survey conducted by Freeman & Henderson (1986).

Case 1

This 20-year old first-year student of divinity had been bingeing two or three times per week for at least 2 years. Periodically, he fasted for up to 6 days at a time and used enemas to control his weight. He also drank great quantities of diuretic tea. He exercised excessively, often spending 3 h/day lifting weights, walking and doing yoga. Unfortunately this subject did not consider himself to be in need of any help and would not cooperate with the assessment programme; however, questionnaire results are available. He had a psychiatric history in his home country (the USA) of psychoanalysis for unspecified problems including drug abuse. He did not complain of any physical effects of his disordered eating. He had no family history of affective disorder. Although this subject knew his eating was abnormal, as required by DSM-III criteria, he felt he had his problems with eating under control and therefore was not afraid of not being able to stop voluntarily. He did not meet Russell's

(1979) criteria for bulimia nervosa, as he neither induced vomiting nor took laxatives to control his weight. He did not have a morbid fear of becoming fat.

Case 2

An unemployed married man, aged 28 years and the father of two children, this subject had chronic kidney failure. He had been receiving dialysis treatment for 6 years. His binge-eating began when he lost his job 2 years before seeking help. When seen, he was bingeing several times per week and occasionally inducing vomiting. He did not abuse laxatives. He was much concerned at the potential harm he was doing himself by bingeing and vomiting, particularly since he invariably binged on foods not included in his therapeutic diet, e.g. bread and jam, chocolate and cakes. Both of his parents were extremely overweight, and this subject himself had been obese as a teenager. His mother then put him on a diet, which consisted in eating only meat, and he lost two stones in weight. He had been a very heavy drinker from the ages of 17 to 19, and at that time also had *grand mal* fits of unknown cause. He liked to eat in the street as soon as he had purchased the sweets, cakes etc. on which he preferred to binge. He said he dreamed of Mars Bars. When angry with his children—aged 1 and 2 years—he never hit them; he threw food at them. He had previously been diagnosed as suffering from a severe personality disorder with obsessional schizoid features. It was not clear how much his physical disorders contributed to his bulimia, but given his past history it was felt he still met DSM-III.

Case 3

A single, second-year chemistry student aged 20, this young man would control his eating for weeks at a time, and then binge and vomit continuously for as long as 5 days. His problems had started when he went to university. Having been very active at school in sports, he found the sedentary student life led to him putting on weight, since he continued to eat the same amount of food as before. This upset him and he began to diet. One morning he found himself to be over-eating at breakfast time and decided to keep on eating and then he induced vomiting. By the time he sought help, he felt his eating during the binge phases was completely out of control. Because he could not attend lectures or go out with his friends at such times, he felt his whole life was being affected, which made him feel very depressed. He would often eat the same meal again and again, e.g. he would have fish, chips and beans in the student refectory, followed by rice pudding. He would then induce vomiting. Having checked that there was no one around who had seen him eat the first meal, he would then eat fish, chips, beans and rice pudding again and induce vomiting. He felt he was more likely to binge when depressed. He had no previous psychiatric history, nor had anyone in his immediate family. He denied any feelings of physical ill-health as a consequence of his bingeing behaviour.

Case 4

A 27-year old community worker, presently employed as a care assistant in a home for mentally handicapped adults, this man had a 3-year history of inexplicable vomiting and regurgitation. During this period he had lost about 15 kg in weight, and was referred to the gastrointestinal unit, which reported no significant findings. About 1 year after the vomiting began, he started to binge—as a consequence, he said, of being so hungry after vomiting. At the time of presentation he was bingeing daily and vomiting about eight times a day. He bent over in order to regurgitate and, although he denied that he vomited on purpose, he admitted that he could not vomit unless he bent over, and sometimes not unless he also pressed his abdomen. He felt guilty about over-eating, as he saw it, and stole food from the kitchens where he worked. He ate secretly in the street to disguise the amount of food he consumed. He admitted that he was very pleased when people commented on how much more attractive he looked since he had lost so much weight.

The patient's problems seem to have stemmed from the period immediately after he and the rest of the family found out that his father, an alcoholic, was also homosexual. Their family was Catholic and deeply religious, and they rallied round to support the father, but the patient was very ashamed. The father's increasingly outrageous behaviour over the next few years, such as bringing his lovers home, etc., had finally caused a separation between the patient's parents. As a consequence, the mother was being treated for depression.

The patient suffered many physical symptoms resultant on his disordered eating; he complained of constant listlessness, cramps and pins and needles in his legs, rashes on his legs and a large number of colds and coughs. He had lost several teeth as a consequence of his frequent vomiting.

He did not meet Russell's (1979) criteria for bulimia nervosa, because he did not have a morbid fear of becoming fat.

Case 5

A 25-year old married man employed as a commis chef, this subject presented with a 2-year history of bingeing, self-induced vomiting, laxative and non-prescribed amphetamine abuse. His eating problems had begun when he was on a diet. He had dieted until he was 70% of normal body weight for a man of his height and age. At this time he found himself eating large quantities of sweets and cakes. He induced vomiting immediately and realised he had found a way to eat what he liked without putting on weight. Latterly he only induced vomiting occasionally and relied on amphetamines to control his hunger and laxative abuse to control his weight. Physical symptoms he experienced included peripheral paraesthesiae, frequent palpitations, severe swelling of the parotid glands, skin rashes, dehydration and occasional severe chest pain. He also complained of loss of energy and spasms in his calf muscles. He sometimes noticed his vomitus to be blood-stained. Although he had no previous psychiatric history or family history of psychiatric disorder, he was found to be clinically depressed, but failed to respond to two different antidepressants.

Procedure

All the subjects were assessed over a period of 2 or 3 weeks, to check that they met DSM-III criteria for bulimia, and to see whether or not they also met Russell's (1979) criteria for bulimia nervosa. They were weighed and their heights noted. A full personal history and history of weight and eating patterns were taken. The BITE (Henderson & Freeman, p. 18, this journal 1987), EAT 40 and EAT 26 (Garner & Garfunkel, 1979; Garner *et al*, 1982) and EDI (Garner *et al*, 1983*a*,*b*) were administered. The BITE is a self-rating 33-item questionnaire designed to detect subjects with bulimia or binge-eating. It has two scales, a Symptom Scale and a Severity Scale, which allow for the measurement of the degree of symptoms present and an index of the severity of bingeing and purging behaviours. The EDI, EAT 40 and EAT 26 are standard instruments, which assess the attitudes and objective features of eating disorders.

Subjects were asked to keep a diary of everything they ate and drank, and of how often they binged, vomited and abused laxatives. They were asked to note the occasions and quantities of other drugs taken, and of how often they engaged in exercise designed to counter the effects of bingeing.

TABLE I
Heights of the subjects and their weights as a percentage of MPMW[1]

		Weight as % MPMW[1]			
Case	*Height (m)*	*Present*	*Highest*	*Lowest*	*Ideal*[2]
1	1.83	109	115	93	96
2	1.76	89	124	79	90
3	1.76	93	101	91	92
4	1.90	89	118	89	100
5	1.85	103	103	79	82
	$\bar{x}=1.82$	$\bar{x}=97$	$\bar{x}=112$	$\bar{x}=84$	$\bar{x}=92$

1. MPMW—Matched Population Mean Weight—the mean weight of individuals of the same age, sex and height, as derived from the tables of the Society of Actuaries found in *Scientific Tables* (Diem & Lentner, 1970).
2. Ideal weight—the subjects' preferred weight

TABLE II
The ages, chronicity and frequency of bulimic behaviour

			Frequency per week of			
Case	*Age of onset (years)*	*Duration of illness (years)*	*Binge*	*Vomit*	*Laxative abuse*	*Other*
1	20	3	3	0	0	7[1]
2	26	2	7	2	0	0
3	19	1	5	5	0	0
4	24	3	7	56	0	0
5	23	2	2	0	7	7[2]

1. Enemas, diuretic tea, excessive exercise.
2. Amphetamine abuse.

Results

Tables I–III show the results obtained by the subjects on the various measures and questionnaires.

Discussion

Physical characteristics

Zinkand *et al* (1984) noted a tendency for bulimic men to be taller and heavier than men without eating disorders, but Herzog *et al* (1984) found them to be lighter. The bulimic men described here were taller and lighter than average (Table I). The thinner subjects' ideal weights were close to their present weights. The two heavier subjects, while of perfectly normal weight, wanted to be much thinner. Herzog *et al* (1984) found a mean age of onset in bulimic men of 18.6 years, while in this sample mean age of onset was higher (22.4 years).

Psychological characteristics

The scores the subjects obtained on the EDI and EAT would not have identified these men as having eating problems. Subjects' scores on the subscales of the EDI were more similar to those of normal than bulimic women. The cut-off scores on the EAT 40 and EAT 26 are 30 and 20 respectively; the subjects' scores were below these. Inspection seemed to indicate that the men's scores on the EAT and subscales of the EAT were between those of normal and bulimic women. It is interesting that these subjects did have scores for bulimia which were well elevated above those of normal men and women on both the EDI and EAT scales. It was on the less objective scales and more on those indicating attitude that they failed to show large differences from normals. One can speculate that this may be in part a result of a response bias operating; the subjects seemed reluctant to mark any response as 'always' or 'never'. Another reason why the subjects' scores were so low may have been that they were upset by the very obvious female bias to the questions in the EDI and EAT scales. One subject simply did not make any responses to the questions in the EDI asking how much one likes the shape of one's buttocks, hips and thighs etc.; another subject had clearly answered these questions at random. One item on the EAT 40 deals with menstruation and this was clearly inapplicable.

It is clear that the subjects' scores would have identified them as being bulimic using the BITE; the cut-off is 25 for the total score. The subjects' scores were much more similar to those of bulimic than to those of normal women.

TABLE III

The subjects' mean scores on the standard eating disorder questionnaires, the EDI (Garner et al, 1983a,b) and EAT (Garner et al, 1979, 1982), compared with norms where available. It includes subjects' scores on the BITE scale developed by Henderson & Freeman (1987)

	Bulimic men	*Bulimic women*[1]	*Normal men*[1]	*Normal women*[1]
EDI				
Desire for thinness	5.4	15.2	1.6	5.0
Bulimia	8.0	11.2	1.0	1.8
Bodily dissatisfaction	7.2	17.4	3.9	9.8
Ineffectiveness	6.8	13.9	1.6	2.1
Perfectionism	3.8	9.9	6.2	5.6
Interpersonal distrust	4.6	7.4	3.1	2.3
Interoceptive awareness	7.6	12.3	1.4	2.3
Maturity fears	1.6	5.9	2.7	2.3

	Bulimic men	*Bulimic women*[2]	*Normal women*[3]
EAT 40	28.5	55.5	15.4
EAT 26	17.8	38.4	9.9
Factor 1: Dieting	8.5	20.8	7.1
Factor 2: Bulimia	6.5	10.6	1.0
Factor 3: Oral control	2.8	7.0	1.9

						BITE scores Mean		
Subjects	*1*	*2*	*3*	*4*	*5*	*Bulimic men*	*Bulimic*[4] *women*	*Normal*[4] *women*
Symptom	19	25	21	20	24	21.8	26.03	2.94
Severity	8	7	6	7	19	9.4	10.16	0.44
Total	27	32	27	27	43	31.2	36.19	3.38

1. Garner *et al*, 1983*b*.
2. Garner & Garfinkel, 1979.
3. Garner *et al*, 1982.
4. Henderson & Freeman, 1987.

Although Herzog *et al* (1984) found evidence that 26% of the men with anorexia and bulimia in their study were homosexual, none of the five men here described admitted to any homosexual interests; all claimed to be exclusively heterosexual.

Cases 1 and 3 refused any treatment. Case 4 is still in treatment. After receiving a kidney transplant and undergoing intensive psychotherapy, Case 2 was still bingeing and vomiting, as was Case 5 after successful treatment with antidepressants.

Conclusion

Bulimia may be more common in men than has previously been supposed. Button & Whitehouse (1981) and Clarke & Palmer (1983) found no evidence of eating disorder in the groups of men they surveyed using the EAT. In view of the results described in this paper, it would seem that caution must be used in the administration of test instruments derived from and devised for women, as the pattern for men does not seem to be as clear-cut. Most of the subjects described here would have been missed if the most widely used instruments (i.e. the EDI and EAT) had been used for screening, yet all subjects had clinically significant and distressing pathology.

Appendix 1

Diagnostic criteria for bulimia nervosa

DSM-III (American Psychiatric Association, 1980)

A. Recurrent episodes of binge-eating (rapid consumption of a large amount of food in a discrete period of time, usually less than 2 h).

B. At least three of the following:

(a) Consumption of high-calorie, easily ingested food during a binge.

(b) Inconspicuous eating during a binge.

(c) Termination of such eating episodes by abdominal pain, sleep, social interruption or self-induced vomiting.
(d) Repeated attempts to lose weight by severely restrictive diets, self-induced vomiting or use of cathartics and/or diuretics.
(e) Frequent weight fluctuations greater than 10 pounds (4.5 kg) due to alternate binges and fasting.

C. Awareness that the eating pattern is abnormal and fear of not being able to stop voluntarily.
D. Depressed mood and self-depreciating thoughts following eating binges.
E. Bulimic episodes are not due to anorexia nervosa or any other known physical disorder.

Russell (1979)

A. Powerful intractable urges to over-eat.
B. They seek to avoid the fattening effects of food by inducing vomiting or abusing purgatives or both.
C. A morbid fear of becoming fat.

Life Events, Vulnerability and Onset of Depression:
Some Refinements

G. W. BROWN, A. BIFULCO and T. O. HARRIS

A prospective study of 400 largely working-class women with children living at home has once again demonstrated the major importance of long-term severe threatening life events in provoking caseness of depression. However, it again shows that only about one out of five women experiencing such an event go on to develop depression at a case level. This paper demonstrates that more sensitive characterisation of severe events can greatly increase the size of this association. This is done both by improving the description of the event itself and by taking into account various ways in which the event can 'match' characteristics of the women present at the first interview, well before the occurrence of the event or any onset of depression.

The Life Event and Difficulty Schedule (LEDS), the full version of which was produced in 1969, has consistently shown large associations between life events and the development of clinical depression in the general population (see Brown & Harris, 1978; 1986). The approach is investigator-based and attempts to deal with the meaning of events for particular individuals. Since bias may arise if a person who has developed depression is asked about the meaning of events, it is based on a *contextual* method of rating events. A judgement is made by the investigator about the likely meaning of the event, given the particular biography and current circumstances of the person, ignoring anything the person says about his or her reaction. Therefore contextual ratings deal with specific meaning in the sense of taking into account the circumstances surrounding a particular event or difficulty. Other commonly used life-event instruments have dealt with general meaning, in the sense that the meaning of a whole class of events (such as a birth) is used irrespective of the context in which the event occurs (Brown, 1981, 1983).

The LEDS is based on a semi-structured interview which is used to gather as full and coherent an account as possible of any incident which may be relevant to the research enquiry. The interviewer establishes the presence or otherwise of 40 types of possible event and also the occurrence of various kinds of ongoing difficulty. A set of previously developed rules is used to decide whether or not an event is to be included. Therefore, there is no question of including the death of a distant relative if this is not already covered by rules about what can and cannot be defined as an 'event'. Once the occurrence of an event or a difficulty has been established, a second level of interviewing allows the investigator to specify various aspects of the meaning of the event or difficulty for the individual. In assessing, say, the threat of having a third child in an overcrowded flat, raters make a judgement of what most persons in such circumstances would be likely to feel, by taking into account what is known of the person's plans and purposes, as these are reflected in his or her biographical circumstances. By ignoring self-reports about meaning, various potential sources of bias stemming from the respondent can be excluded. However, some of what is gained in terms of controlling bias may be lost in terms of precision of measurement. Much potentially valuable information must be ignored; strict rules do not permit feelings of, say, attachment or commitment to be taken into account when the degree of stress is assessed contextually. Since the presence of depression or the recent experience of a loss may inflate the reported amount of previous attachment to the lost object, such information cannot be used safely. This style of measurement is particularly concerned with controlling respondent biases often overlooked by other methods, but it also guards equally against various investigator biases. Manuals which give strict definitions of which incidents can be counted as events, and directories giving thousands of examples of precedents of contextual meaning, rated on the various scale-points (such as threat or loss), are designed to prevent interviewers from allowing knowledge of the respondent's symptoms or reported emotional responses to influence their ratings. Consensus meetings of other interviewers in the research team, who are blind to the subject's symptoms and reactions, provide a further check on investigator bias. The approach to difficulties is basically the same (Brown & Harris, 1978).

'Severity' of threat in the LEDS is assessed in terms of the immediate or more long-term impact of events and the ongoing impact of difficulties, but the first stage of the instrument that establishes their presence can be used as a basis for the measurement of a variety of other qualities, such as loss, danger and chances of resolution. Only one type of event has proved so far to be of central aetiological importance for depression—events which are *severe* on long-term contextual threat. They are in fact defined by two rating scales. They must be rated '1—marked' or '2—moderate' on a four-point scale of long-term threat, judged in contextual terms about 7-10 days after the event's occurrence, and must also be focused on the subject—either alone or jointly with someone else (Brown & Harris, 1978). Also only a restricted class of difficulties—termed *major* difficulties—appears to be of critical importance for depression. These must be at least marked (1-3) on a six-point scale of unpleasantness, involve non-health problems and have lasted 2 years (Brown & Harris, 1978). However, physical health difficulties are included occasionally as a major difficulty if they restrict a subject's plans or activities in some critical way: for example, causing her to give up a job, move house or postpone marriage, either in the case of her own physical health because it presents so serious a difficulty, or in the case of other people's health because she is involved in continuous responsibility for their care and supervision. These *provoking agents* form only a small minority of the events and difficulties recorded by the LEDS instrument.

There has been a good deal of uncertainty about the importance of the aetiological link between life events and the onset of depressive disorders. Results of research have been presented for the most part in terms of the apparently straightforward notion of 'variance explained' (r^2). The amount explained in these terms is invariably low even when an investigator-based instrument such as the LEDS is used. The percentage is usually no more than about 10% (for checklist respondent-based instruments it is considerably lower [Brown & Harris, 1986]). In the light of this, some have concluded that "life events are unlikely to have clinical or preventive importance" (Andrews & Tennant, 1978). However, the same conclusion would have to hold for aetiological agents of accepted importance such as heavy smoking and lung cancer. The paradox is simply the result of the fact that such an index takes into account that most heavy smokers do not develop lung cancer (and that most with a provoking agent do not develop depression). However, most instances of caseness of depression, when strictly defined, do have a severe event or major difficulty occurring before onset, just as most instances of lung cancer are associated with heavy smoking. An index frequently used in epidemiological research, Levin's attributable risk percentage, reflects this since it gives the proportion developing a condition that is associated with the putative causal risk factor, allowing for the fact that in some instances it will be associated by chance (Cole & MacMahon, 1971; Markush, 1977; Brown & Harris, 1986).

A review of onset of caseness of depression in 10 population studies of women in the general population, using the LEDS and similar high thresholds for defining a case of depression, shows that all agree that the majority of women experienced a provoking agent before onset. The actual proportion having a provoking agent ranges from 62 to 94% with an average of 83% (Cooper & Sylph, 1973; Brown & Harris, 1978; Brown & Prudo, 1981; Finlay-Jones & Brown, 1981; Costello, 1982; Campbell *et al*, 1983; Bebbington *et al*, 1984; Brown *et al*, 1985; Parry & Shapiro, 1986). The average attributable risk percentage is 73%. While this should strictly allow for the differences in length of the study period, it serves as a reasonable approximation of the order of effects that have been found (Brown, 1986).

However, the use of 'variance explained' does remind us of the need to understand why only about one out of five women experiencing a provoking agent goes on to develop depression at a caseness level. In recent years, most of the effort to explain this differential response has been channelled into exploring the role of vulnerability factors such as low self-esteem or lack of social support. In the way that we have used the concept of vulnerability, such factors are only associated with an increased risk when a provoking agent is also present. In this paper we explore a complementary approach—one that seeks to improve the sensitivity of the current LEDS contextual measures of threat. The paper uses material from a prospective enquiry. First, we deal with information concerning events and difficulties collected at the time of the follow-up interview—that is with additions to the current LEDS schedule. Later, material collected at the first interview is used to characterise these same events; this latter exercise can therefore only be carried out in a prospective enquiry.

Design of the enquiry

Working-class women with a child at home and living in an inner-city area (Islington, North London) were selected since research had suggested that they are particularly likely to develop depressive disorders (Brown & Harris, 1978). The cooperation of general practitioners was enlisted and they sent an introductory letter together with a screening questionnaire to women aged between 18 and 50 years, explaining the nature of the research. Women were only rejected if they did not meet the criterion of being from European or Caribbean backgrounds, having at least one child under 18 years of age living at home and a spouse or cohabiting partner who was in a manual occupation (Goldthorpe & Hope, 1974). In addition, all single mothers were included regardless of occupational or class criteria, as there was evidence that such women have a high rate of depressive disorder (e.g. Moss & Plewis, 1977; Surtees *et al*, 1983). For separated, divorced and widowed women who were living as 'single parents', the husband's occupation was taken to define class status if he had lived with the woman in the previous five years. For all other women not living with a man, their own current occupation was taken (for details, see Brown *et al*, 1986*a*).

The screening process identified 435 suitable women, of whom 91% (395/435) completed the first stage of the survey. The main investigation was conducted in two phases, approximately 1 year apart. In the first phase, measures of the quality of personal ties, support received and self-esteem were collected, together with an account of psychiatric disorder both at the time of interview and in the preceding 12 months. Two interviews, lasting in all between 3 and 4 hours, were usually necessary (O'Connor & Brown, 1984). The second phase comprised measures of life events and difficulties occurring during the follow-up year, together with actual social support received during any significant crises and the woman's response to it and details of any psychiatric disorder over the follow-up year. Severe life events and marked difficulties in the year before the first interview were also covered. Previous work suggests that these can be collected reliably over such a period of time (Neilson, 1984). A full interview was completed for 89% of the women.

A shortened version of the Present State Examination (PSE) instrument was used to collect material about basic symptoms (Wing *et al*, 1974; Cooper *et al*, 1977). Although the PSE was initially designed to cover the month immediately preceding interview, it was possible to modify the approach to examine the past 12 months, probing for episodes of distress and then collecting details about symptoms for any episode of affective disorder, even if this had cleared up by the time of interview. Once symptoms had been collected, indices of severity and diagnosis were derived by presenting the PSE symptoms to a panel of experienced raters who were blind to possible aetiological factors. Subjects considered to have had definite psychiatric disorders are classified as *cases* for the periods involved. For caseness of depression, at least four core symptoms are required in addition to depressed mood (Finlay-Jones *et al*, 1980). In all instances, many other symptoms were also rated and, in Islington, women judged to be cases of depression had an average of 19.1 (Brown *et al*, 1985). Experience with the PSE over the last 15 years does not leave much doubt that such cases are broadly at the level of severity of conditions treated by psychiatrists in outpatient practice. This threshold for caseness has recently been compared with two other well known thresholds, the Research Diagnostic Criteria (RDC) (Spitzer *et al*, 1978), and the ID threshold of the PSE (Wing & Sturt, 1978) in an extensive population study in Edinburgh. The Bedford College criterion for caseness was found to be higher than those of the ID/CATEGO system of other PSE users and the 'major depressions' of the RDC (Dean *et al*, 1983).

New measures

For cross-sectional analysis

Refinement of the severity threat rating

Only one addition to the rating of threat was introduced for the Islington survey. This was a straightforward extension of the present rating. A simple 'upper' and 'lower' division of severe events was developed with anchoring examples. An example of 'lower' is a woman working as a secretary, whose husband is warned of likely redundancy and where jobs in his specialised occupation are difficult to get. The event was rated low because the woman had a full-time job and the redundancy had not yet occurred. An 'upper' severity rating would be given to an event where redundancy had actually occurred and was already giving rise to considerable financial problems affecting the family.

Loss and danger

Two four-point ratings of loss and danger were developed in a previous study, although minor amendments were made to the loss rating for the current project (Finlay-Jones & Brown, 1981). Six classes of experiences among those with a severe event were considered to involve loss: (a) death, (b) separation, (c) loss of employment of subject or 'chief wage-earner', (d) loss of material possessions, (e) loss of physical health by subject and (f) loss of a cherished idea. The last included either disruption of a woman's expectation of a key person's commitment, faithfulness or trustworthiness, an event which might lead the subject to question these qualities in herself (e.g. learning her daughter has been taking heroin) or incidents that may be an even more fundamental challenge to identity (e.g. discovering that her husband is bisexual). Also included among losses are disappointments defined as severe events leading to a reversion of a previously unpleasant situation following a period when the problem had been dormant or had improved, and where it had apparently been reasonable for the subject to assume there might have been some more or less permanent change for the better. Events were not included where there had been no such revision and where the event underlined, as it were, the loss of a particular 'cherished idea' that had occurred more than 1 year before. Only a handful of 'disappointment' events were added to the total loss events. A second and independent rating was made of 'danger' which was defined as the degree of unpleasantness of a specific future crisis which might occur as a result of the event.

Chances of resolution

Each difficulty was rated on a nine-point scale in terms of the chances of its resolution. The ratings were considered in contextual terms, taking into account possible intervention by the subject or someone else. The rating also considered whether any resolution would be likely to involve other serious problems in the process. The scale has been used here as a simple dichotomy, contrasting difficulties considered to have at least some chance of resolution (or where it was unclear) with those which had little or no chance without creating major additional problems—that is 'low' chances of resolution.

'Matching'—difficulties

One major innovation is an attempt to explore the fruitfulness of the notion that the risk of depression is increased after a severe event when there is a *match* with certain characteristics of the woman and her life-context at the time of the first interview. At heart, the notion deals with the congruence of the meaning of the event, judged in contextual terms, with some earlier state. Three areas were considered as a basis for matching. One concerned marked difficulties present at the time of the first interview (as well as at the point when the event occurred) and is therefore referred to here under the heading of measures that can be used in cross-sectional analysis. The remaining two concerned commitment and conflict and required a prospective design.

For use in prospective studies

Commitment

At the first interview, each woman discussed at considerable length five areas of her life—children, marriage (or living with someone), housework, employment and other activities outside the home. For each area she was rated on a four-point scale in terms of her *commitment*. This concerned the idea of the role or activity rather than particular personal relationships or actual current activities. For example, like other women, single parents were rated in terms of their commitment and enthusiasm about the idea of marriage (or living with someone). But if a woman chose to express her commitment (or lack of it) in terms of her current situation we took this into account. For example, when a woman was married, the nature of her relationship with her husband often dominated her answers to our questions. We took such comments into account but also kept in mind that it was possible for a woman to be highly dissatisfied with her actual experiences in a given area and yet be committed to the idea of that area as worthwhile in general. For the present exercise, a woman was considered committed to a particular area if rated '1—marked. In addition, we asked women in detail about any relationship (other than with husband or child) they named as 'very close'. All but one-fifth of the women named someone and the average number was two (O'Connor & Brown, 1984; Brown *et al*, 1986*a*). Since we did not develop a rating of commitment for such ties, we counted a woman as committed if she rated '1—marked' on a four-point scale of dependency, made for every such close relationship. Although the notion of commitment is broader than that of dependency, the latter provides a reasonable approximation for the present exercise.

Role conflict

Role conflict was rated at first interview, particularly any arising from diverging obligations, such as that between domestic and external spheres. Conflict had to be reflected directly in the woman's actual social circumstances (e.g. full-time work *vs* time spent with children), although its rating in each instance was based on the feelings she expressed about it (Brown & Bifulco, 1985). Thus, a high role conflict rating ('1—marked' or '2—moderate' on a four-point scale) was given where a woman reported feeling strain or psychological tension between two such domains in her life, both of which made demands on her. Role conflict was also rated where strain was reported by the woman in the way she related to others: for instance, if she experienced conflict over having high hostility as well as high dependency needs in her key relationships, or if her desire to get close to people conflicted with her mistrust of others.

Response to severe events and difficulties in terms of hopelessness

A four-point rating of feeling of hopelessness in relation to a particular event or difficulty (or complex of related events and difficulties) was made. One rating involved the predominant pattern during the year and the other the woman's outlook towards the end of the follow-up period. This enabled us to characterise the response at the beginning of any crisis arising in the year and to take account of any change that might occur in the response to a subsequent life event that might precede an onset of depression. The ratings take into account the woman's reported response to her life as a whole in the context of the crisis. Therefore, hope could be high in spite of a devastating loss or an irresolvable difficulty, in the sense that feelings of hopelessness were not generalised to life as a whole. However, the rating gave special weight to the women's response to the particular crisis. Figure 1 gives a schematic outline of the basic ratings in terms of the two interviews—we use the terms *D-event*, *C-event* and *R-event* for matching difficulty, commitment and role conflict events respectively.

Reliability of measures

The inter-rater reliability of the well established measures such as the PSE has been shown to be high (Cooper *et al*, 1977; Wing *et al*, 1977). Similarly the occurrence, severity and dating of life events and difficulties have shown high inter-rater agreement, as well as high inter-respondent agreement, when a patient and a close relative have been interviewed separately by different interviewers (Brown & Harris, 1978, 1982; Tennant *et al*, 1979; Parry *et al*, 1981). High inter-rater reliability of loss and danger ratings has also been demonstrated (Finlay-Jones & Brown, 1981).

For measures new to the current study, the inter-rater agreement has also been high. When 20 interviews were rated independently by different raters, agreement on the 'upper' and 'lower' threshold of events reached 0.70 agreement (on kappa) and the scale measuring resolution of difficulties showed complete agreement. In terms of the

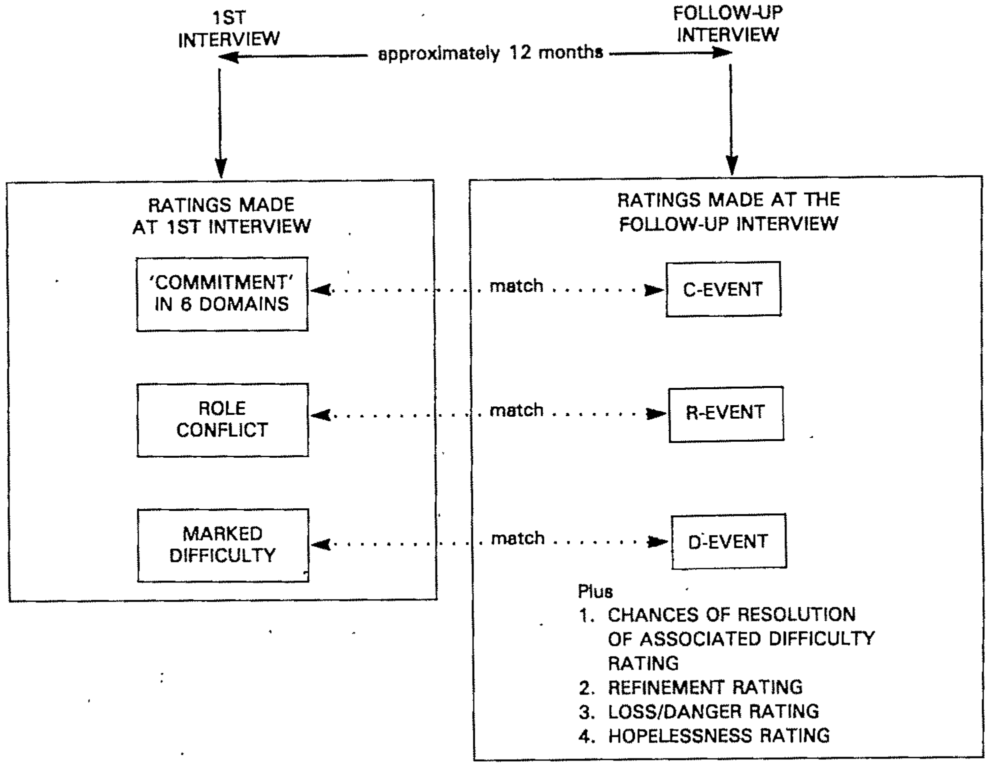

FIG. 1. Schematic outline of the ratings for key severe events.

matching scales, agreement on commitment also reached a satisfactorily high level (e.g. commitment to marriage reached a kappa of 0.89 and motherhood 0.88) as was role conflict (0.79).

A full inter-rater reliability of the hopelessness measure has not yet been undertaken, but inter-rater agreement on ratings based on transcribed descriptions was 0.80.

Results

In order to establish the causal importance of provoking agents, it is necessary to consider all 303 women followed up who were not suffering from depression at first interview. However, most of the questions tackled in this paper are concerned with whether this present measure of severe event can be improved and here it is sufficient to consider only the 130 women with a severe event in the follow-up year (or in some instances the 150 with either a severe event or major difficulty). The 26 weeks before onset has been taken for onset cases; but in order to maximise the number with a severe event, thereby increasing the sensitivity of the analysis, the whole follow-up period has been taken for those without an onset. (However, for the calculation of attributable risk percentage this would be misleading and a 6-month period must also be taken for those without onset.)

Retrospective measures

Refining the rating of severe event in the light of material collected at follow-up

Provoking agents in Islington were highly related to onset of depression. Of the 32 women with such an onset in the follow-up year, 29 had a severe event in the 6 months prior to onset; a number of studies have now concluded that severe events of aetiological importance almost always occur within 6 months of onset (Brown & Harris, 1986). One further woman had a major difficulty as her only provoking agent. We will concentrate first on the nature of the severe events occurring in the sample as a whole (see Table I). One simple descriptive rating of the LEDS divides events into nine categories involving either an interpersonal crisis with (1) husband or lover, (2) close relative or friend, (3) child, (4) the death of someone close, (5) a pregnancy or birth to the subject, (6) health of subject, (7) health of close relative or friend, and two broad-based categories, (8) involving work, housing or material deprivation and (9) a small number of miscellaneous crises such as burglaries. The scheme is crude and sometimes ambiguous in the sense that some events straddle more than one category—for example, a pregnancy rated severe because of the woman's poor housing and economic deprivation was rated here under 'pregnancy'—but it serves to give a general

TABLE I

Severe events[1] in terms of broad descriptive categories.

	Women without onset (101 women & 130 events) % events		*Women with onset (29 women & events) % events*			*Onsets in event category % onset*
Relationships						
1 Husband/lover	23	59	38	79	23	27 (11/41)

	100		100			

1. All events other than 'linked' events are included, except for onset cases, where only the event preceding the onset is considered.

introduction to the range of incidents covered by severe events. All severe events occurring in the follow-up year have been taken for women without an onset of depression. However, if events were 'linked' to each other, only one was taken (e.g. a death of a father counted and not first learning of his cancer), or if there was more than one event in any one of the nine categories (e.g. a daughter found taking drugs and a son sent to court—both in category 2—'child'), this was again counted only once. Of the 130 severe events occurring to the 271 women without an onset, 59% involved interpersonal crises, 6% a pregnancy or birth, 9% health of the subject or a close relative, and 25% other events largely concerning work, housing or material deprivation (Table I).

For women with onset of depression, the severe event occurring nearest to onset was classified. Table I shows that the 29 depressed women with a severe event experienced more interpersonal crises than other women (79 *vs* 59%; $P<0.05$). Such interpersonal events, together with those involving a pregnancy or birth, were more likely to be associated with an onset of depression (23% [23/101] *vs* 8% [3/48]; $P<0.02$: Table I).

It has been clear from this kind of evidence that severe events are sometimes of a kind that are unlikely to provoke depression and this is why we developed the simple refinement of severe events into 'upper' and 'lower' categories. However, once we turn to characterising women in terms of events, there is a problem because they could experience more than one. Therefore, further *ad hoc* rules had to be developed to characterise women (rather than events). For instance, in dealing with the refinement of the severity rating, we characterised a *woman* as 'upper' if she had a severe event rated 'upper' at any time in the 6 months before onset of depression or in the 12 months before interview for other women. Those with a severe event in the upper division had a four-fold greater risk of depression (28% [27/98] *vs* 6% [2/32]; $P<0.01$).

However, this refinement of long-term threat rating does not take us very far, and we next turn to the rating of loss. There is widespread agreement that it is particularly the experience of loss that is involved in the onset of depression and a recent study using the LEDS to compare depression and anxiety conditions confirmed this (Finlay-Jones & Brown, 1981). In this study in a general practice setting in North London, depressive conditions tended to be preceded by severe events involving loss, and anxiety states by those involving danger. Similar results were found in a study conducted in Edinburgh, where severe life situations involving personal loss were highly predictive of depressive symptoms and those involving threat predictive of anxiety symptoms (Martin & Ingham, 1985). In the current study in Islington, we characterised a woman as having a loss if such an event occurred in the 6 months before onset or the year before interview for other women. Severe events involving loss defined in this way were more likely to be associated with depression (27% [24/88] of loss *vs* 12% [5/42] of non-loss women; $P<0.05$). Nevertheless, it should be noted that women in the non-loss group still had a higher risk of depression than those without a severe event (i.e. 12% [5/42] *vs* 2% [3/173]; $P<0.01$). When loss and the 'upper' *vs* 'lower' severity rating are both taken into account, there is a five-fold difference in rate of onset

TABLE II
Onset among 303 women in terms of presence of a provoking agent and some of its characteristics

	% onset	
No provoking agent	1 (2/153)	
Provoking agent:		
Major difficulty only	5 (1/20)	20 (30/150)
'Lower' severe event	6 (2/32)	
'Upper' severe event: non-loss	16 (4/25)	
'Upper' severe event: loss	32 (23/73)	
$P<0.001$	11 (32/303)	

among those with a severe event (Table II). 'Upper' events involving loss have a rate of 32%; 'lower' severe events with a risk of depression of 6% do not differ from major difficulties without severe events which have a risk of 5%. However, the latter two groups still had a four-fold greater risk of depression than those women with no provoking agent at all.

'Matching' of severe events with a difficulty present at the first interview

After the follow-up interview had been rated, a decision was made for every event, whatever its threat rating, about whether or not it was 'linked' to an ongoing difficulty and these were used later as the basis for the matching exercise. These 'link' ratings were made by a worker specially employed for the task and not involved in the original data collection and who was therefore blind to the information about symptoms and subjective responses. Difficulties are a source of events, since they tend to throw up events throughout their course. However, the criteria for deciding whether an event was linked with a prior difficulty did not require a *causal* relationship between the two, though this might well be present. For example, an event would be considered 'linked' if it had only been rated severe because of the presence of the difficulty. Thus a pregnancy rated severely threatening because of poor housing would be considered to be linked to the prior housing difficulty.

For the matching exercise itself, severe events and marked difficulties present at the first interview were considered. A period of 6 months and not 2 years was taken for the length of difficulty, as we did not wish to prejudge the relevant length of time, and on grounds of common sense this appeared to be long enough to differentiate a difficulty from events arising 'on their own'. In order to check whether the 'link' records were adequate to embody the notion of events 'matching' difficulties, we reconsidered the written accounts of the women with a severe event so that we could decide if any severe event not rated as 'linked' could be held to 'match' difficulties. At this stage, three further links were identified on the basis that the *meaning* of both the event and the difficulty for the subject and the implications for her life plans were critical for deciding on matching. In the majority of instances, difficulty and event were related in a straightforward sense (e.g. a husband leaving home in the background of a history of marital disputes over his heavy drinking and violence). Of the 130 women with a severe event, 35 had at least one matched to a prior marked difficulty (i.e. rated 1–3 on contextual severity and not involving health) that had lasted at least 6 months at the point of the first interview. (Under the LEDS, any health difficulty that creates major interference with any of the roles of the subject is considered to have non-health aspects and has been included in this exercise.)

Our experience suggests that because ratings of difficulties are 'harder' than those of commitment, or role conflict, D-events can be rated accurately enough in retrospect (Brown & Harris, 1982; Neilson, 1984) and thus do not demand a prospective design. In fact, for reasons of pressure on time, the ratings of difficulties were only made at the follow-up interview. However, in no case was a marked difficulty at the time of the first interview rated later without there being indications in the first interview material that it was already present at the earlier date. Thus there is unlikely to be any bias in the dating of these difficulties as a result of the respondent's subsequent experience of a linked severe event and/or depression in the follow-up year.

TABLE III
Onset among the 130 women with a severe event in terms of matching

	% onset
Severe event matching prior difficulty (D-event)	
Yes	46 (16/35)
No	14 (13/95)
	22 (29/130) $P<0.001$
Severe event matching prior commitment (C-event)	
Yes	40 (16/40)
No	14 (13/90)
	22 (29/130) $P<0.01$
Either C-event or D-event	
Yes	37 (24/65)
No	8 (5/65)
	22 (29/130) $P<0.001$

Women with such a *D-event* had a three-fold greater chance of developing depression (Table III). However, severe events occurring at the same time as a marked difficulty to which they did not match showed no increase whatsoever in the risk of depression. Of a total of 35 D-events, 37% concerned a husband or boy-friend, 26% a child, 31% finance or housing and 6% the subject's health. (The original computer-based exercise gives an almost identical result.)

Prospective analyses using earlier ratings

'Matching' of severe events with commitment at the first interview

A second form of matching concerned commitment at the time of first interview. All but 18% (54/303) of the 303 women followed-up had at least one marked commitment in one of the six areas with an average for the whole sample of 1.52. A total of 31% (40/130) of those with at least one severe event occurring in the follow-up year had one that *matched* an area in which they had earlier showed marked commitment and where it was reasonable to assume that the event would threaten any sense of worth, security or sense of hope the woman derived from the commitment or activity associated with it. We read all the written notes of the interview concerning both the commitment rating and the event before making a decision. However, in the majority of instances the decision could have been made by a simple comparison of the area of commitment and the 13-point shortened classification of the event and whether they logically belonged together (e.g. commitment to motherhood—child event). (In the case of someone named as very close, the event had to concern the person for whom the subject had been rated markedly dependent.) But there were some situations where the matching could not be done without taking account of more information. For example, loss of a job by a husband when the firm was also issuing redundancies to other workers was not considered to match high commitment to marriage, because we did not judge that in itself the event would threaten any sense of worth arising from the marriage, but we did include losses of jobs which in some way could be related to a husband's unreliability.

Women with a severe event that *matched* an area of marked commitment (a *C-event*) were almost three times more likely to develop depression (Table III, $P<0.01$). As a check on possible bias, since the decision concerning matching did at times involve an element of interpretation, we carried out a supplementary analysis based only on the simple matching of labels, employing a 38-point basic classification, a condensed version of which appears in Table I (Brown & Harris, 1978). In two instances, however, it was necessary to look up what or who was involved (one where the event was rated as 'goal disappointment' and one where it involved a 'key person from the past'): otherwise the exercise could have been carried out by computer with identical results. This much cruder matching exercise still resulted in a large difference in risk of depression (35% [14/40] *vs* 17% [15/90]; $P<0.02$) indicating the basic result was not biased in favour of our hypothesis by the interpretative nature of the matching exercise.

The two types of matching severe events dealt with so far, C-events and D-events, were uncorrelated (kappa = 0.02; NS). The overlap between them due to chance covered 31% of D-events and 17% of C-events. A woman with either type had a four-fold greater risk of depression than women with a non-matching severe event (Table III). Furthermore, as many as 80% (24/30) of those developing depression after a provoking agent had either a C-event or a D-event.

TABLE IV

Onset of depression among 150 women with a provoking agent in terms of the presence of a D-event (i.e. severe event matching a marked difficulty) and a major difficulty

	Type provoking agent (i.e. severe event or major difficulty)		
Major difficulty	*D-event % onset*	*Non-D-event % onset*	*Major difficulty without event % onset*
Yes	46 (13/28)	7 (1/14)	5 (1/20)
No	43 (3/7)	15 (12/81)[1]	—

1. Six women had a marked difficulty lasting 6–24 months and one had an onset.

One final point should be made about the role of difficulties. Most of the D-events were linked to difficulties that had gone on for at least 2 years rather than only 6 months (i.e. were major difficulties and therefore 'provoking agents') (Table IV). The presence of a major difficulty when an accompanying severe event did not match it did not raise the risk above that for women with a severe event alone—7% (1/14) and 15% (12/81) respectively (Table IV).

All four amendments to the basic severe event rating discussed so far make an independent contribution to onset (Table V)[1]. The risk is particularly high among those with both a C-event *and* D-event (73% [8/11]) and there is a 20-fold difference between them and those with the least risk (i.e. with a 'lower' severe event or only a major difficulty).

TABLE V

Onset among 303 women by characteristics of provoking agent

	C-event (event matching prior commitment)		
Type of provoking agent	*Yes % onset*	*No % onset*	*Total % onset*
1. D-event (severe event matching prior difficulty)	73 (8/11)	33 (8/24)	46 (16/35)
2. Both 'upper' *and* loss event (& not 1)	44 (7/16)	14 (5/35)	24 (12/51)
3. Remaining provoking agents	8 (1/13)	2 (1/51)	3 (2/64)
4. No provoking agents	—	—	1 (2/153)

---

[1] This result and that following for Table VI are confirmed by logistic regression. Copies of all such analyses can be obtained from the authors.

Matching events with role conflict at the first interview

In an earlier analysis, we dealt with role conflict at the first interview and the raised rate of depression following a matching severe event in the subsequent year — an R-event (Brown & Bifulco, 1985). Such role conflict arising from diverging obligations, particularly between domestic and external spheres, was related to risk of depression. Among those with a provoking agent, one-third of those with role conflict developed depression compared with half this rate for those with no such conflict (Brown & Bifulco, 1985). Further analysis indicated that this increased risk was explained by the 'match' between the life event preceding onset and the conflict present at the first interview (43% [9/21] of women with a matching R-event and 18% [20/109] of those without developed depression; $P < 0.02$). For instance, a single parent whose conflict arose from the clash between the obligation to work and the obligation to be a good mother developed depression when she found out that her school-age daughter was pregnant, thus underlining her failure in one of her obligations. R-events and C-events were quite unrelated. However, R-events were highly related to D-events and, since only two instances of depression occurred for women with an R-event and without a D-event (and only one with a C- and a D-event), we have not included R-events in our current model. A total of 37% (13/35) of D-events and 8% (8/95) of non-D-events were R-events ($P < 0.001$); and 18% (7/40) of C-events and 16% (14/90) of non-C-events were R-events (NS).

Vulnerability: self-evaluation

As predicted on the basis of earlier research, it has also been established that a measure of low self-esteem made at first interview (negative evaluation of self [NES]) acts as a vulnerability factor in the sense that risk is increased only when there is a provoking agent (Brown & Bifulco, 1985; Brown *et al*, 1986*a*). However, Table VI makes clear that, except where both a C-event and a D-event are present, negative evaluation of self does increase risk for women in the categories defined in terms of event characteristics given in Table V (see footnote 1).

TABLE VI

Onset among 150 women with provoking agent by its characteristics and prior negative evaluation of self (NES)

	C-event (severe event matching prior commitment)			
	Yes		*No*	
	NES		*NES*	
Type of provoking agent	*Yes* *% onset*	*No* *% onset*	*Yes* *% onset*	*No* *% onset*
1. D-event (severe event matching prior difficulty)	63 (5/8)	100 (3/3)	45 (5/12)	25 (3/12)
2. Both 'upper' *and* loss event (& not 1)	67 (4/6)	30 (3/10)	27 (3/11)	8 (2/24)
3. Other provoking agent	0 (0/4)	11 (1/9)	8 (1/13)	0 (0/38)
	50 (9/18)	32 (7/22)	25 (9/36)	7 (5/74)

Anterior year results

Material was collected at the follow-up interview about events and difficulties in the 12 months *before* first interview. Therefore it was possible to repeat the analyses concerning characteristics of severe events for this anterior year. It was not possible to do this for findings concerning commitment or role conflict, since such ratings should be made at a time prior to the events concerned. However, for the cross-sectional measures, results were closely comparable. Of the 33 women with an onset in the anterior year, 25 had a severe event in the 6 months before, and for 95% (24/25) of these, at least one was 'upper' on severity; 72% (18/25) had one concerning a loss and 48% (12/25) one arising from a marked difficulty, a D-event. The same results already given for the follow-up year were 93, 83 and 55% respectively. A total of 72% of the events nearest to onset (18/25) involved an interpersonal crisis compared with 79% in the follow-up series.

Some examples

In order to illustrate the various ratings we have outlined so far, we will give three examples of women coping with a severe event. They have been selected to involve the same category of event — 'child' (see Table I). The examples illustrate the two extreme risk categories in Table VI and an intermediate one.

Marked risk (63% onset cases [5/8] — Table VI)

Mrs Steven had been widowed 3 years and had three children in their teens living at home. She had had a very difficult childhood, involving loss of parents and violence. When seen for the first time, she had many problems. For example, her electricity and gas had been cut off in the year as part of her chronic and major financial difficulties and her 16-year old son had been put on probation for violent and destructive behaviour and the resulting difficulty, which had lasted for 6 months by the time of our first interview, had been rated 'marked' with 'no or little chance of resolving'. She was rated as having negative evaluation of self. (She felt no good as a mother ["too soft"] and not much good as a housewife ["hopeless at budgeting"] and blamed herself over her son's delinquency). She had a few depressive symptoms and these were enough for her to be rated a borderline case of depression. She also had marked anxiety symptoms. She was rated as marked in her commitment to motherhood (e.g. "the first thing is the kids"; "I would have felt terrible if I couldn't have had the kids"; "I wouldn't have minded staying single if I could have had them"). At follow-up she had had an onset of caseness of depression just after appearing in court for not keeping up her contributions to paying for her son's £400 fine. The court told her, she said, that the penalty was 60 days in prison and this stood if she got behind again. It was a C-event given her commitment to motherhood and 'upper' in severity. Since her son had been a marked difficulty for a number of years with little or no chance of resolution, it was *also* a D-event. She had not expressed role conflict about her children and therefore it was not an R-event. The event itself was not considered a loss. Her son's behaviour had already previously led to her 'losing' important good ideas about him and there had not been a recent improvement that would justify a rating of loss in the sense of a 'disappointment'. However, it was rated '2—moderate' on 'danger' because of its threatening future implications. She was rated as having no hope: she reported she saw no way out as she simply did not have the money. Although she felt very angry at the court's behaviour, she still blamed herself and said she felt ashamed. The event appeared to reinforce prior feelings of failure.

Moderate risk (25% onset [3/12] — upper row, Table VI)

Mrs Rice was divorced with three children in their teens, but showed marked commitment to her work and to nothing else. She felt she had been a good mother and that her children were a credit to her. She was not rated as showing negative self-evaluation although she made some negative comments (e.g. "I'm too soft" and "not really efficient"). However, in the year before interview, her son of 17 had left home after a row which upset her greatly. This had been followed by a depressive episode at caseness level, but by the time of the first interview she showed only symptoms of anxiety. The difficulty at this time was rated 'marked' and 'unclear about chances of resolving'.

During the follow-up year her son was arrested for shoplifting. When she saw him for the first time in 6 months after this there was "shouting and swearing" and onset developed soon after the event. She was considered to have a D-event since the difficulty in her relationship with her son had lasted 6 months at first interview. The event was 'upper' on severity and a 'loss' since he had not been in trouble with the law before. Her initial reaction to her son leaving home had been to feel "bleak but not hopeless", but in response to his arrest in the follow-up year she was rated as having no hope ("there was nothing I could do to put things right"; "prison here he comes"). She did not feel "100% responsible", but it was "one more failure totted up". She had also expressed conflict concerning children at first interview—"it has been a battle between the children and studying". "I've been inclined to put them first, but they've been difficult to cope with." "In an ideal world I wouldn't have had any". Thus, this was also an R-event.

Low risk (0% onset cases [0/38] — Table VI)

Mrs Gordon was a 38-year old married woman with three teenage children at home and a full-time job. When seen at first interview, her self-evaluation was rated as positive ("I'm very confident." "I'm extrovert and cheerful." "I'm natural—nothing special—just me") with only a few minor negative comments ("I'm not a very decisive person"). She reported no role conflict, and the only commitment rated 'marked' was to her work ("I'm very involved with my work, I don't think I could ever give up work. I think it's important for a woman to have a job"). Her commitment to both marriage and motherhood were low. Her marriage was rather poor with low confiding and frequent arguments and now that her children were older, she felt they could look after themselves and required less of her attention.

In the follow-up year, Mrs Gordon's 18-year old son was involved in a fight while he was out for the day at the coast. The police were involved and he was charged with assault and ordered to pay £100 fine. However, Mrs Gordon heard nothing of this until a few weeks later, by which time her son had made arrangements to pay the fine out of his wages and this was being deducted by his employer every week. Mrs Gordon only heard about the affair when the employer rang her for certain details he required about her son.

This event was rated as 'lower' on threat largely because, by the time Mrs Gordon had heard about it, the penalty for the offence had already been determined and her son had clearly already coped well with the situation. She reported being quite optimistic about the future. However, it was rated high on loss since it was the son's first offence and therefore involved the loss of a 'cherished' idea in our terms—of a son as a responsible and reliable young adult. Because Mrs Gordon had no role conflict centred on her children, only low commitment and no prior difficulty, this did not constitute a matching event. Her psychiatric state remained 'normal' throughout.

Further analysis

The interpretation of the results concerning severity and loss appears to be straightforward and requires little further comment. In earlier research it has been only the small minority of events involving severe long-term threat that have raised the risk of depression, and the 'upper' and 'lower' threshold merely adds a refinement to the definition of a severe event. The result concerning 'loss' replicates that of the earlier study of depression and anxiety (Finlay-Jones & Brown, 1981) and also confirms a widespread belief in the critical importance of loss for the development of depression. We can only add at this point that half of the loss events (44/88) involved failure if this is used in the sense of a rejection, a major row or of involving an incident such as an examination failure or divorce.

The interpretation of C-events involving a prior marked commitment also appears to be straightforward. The idea underlying the contextual ratings of events is that the degree of threat reflects the likely impact on the respondent's plans and purposes and that threat will be greater to the degree that the person's sense of self is caught up in these. The importance of the biographical material underlying the rating is that it can be used to make an indirect assessment of such prior plans. A *direct* assessment of prior attachments and commitments is ruled out by the fact that reports of these some months later can never be guaranteed to be free from inaccuracies of memory. Particularly when other circumstances have changed in the intervening period, a respondent may distort the degree to which she was previously committed. Since the commitment ratings were made at the first interview before onset of the depressive condition, they are a *direct* and unbiased

TABLE VII

Marked commitment in at least one area at the first interview by presence of a provoking agent, negative evaluation of self (NES) and onset for those with a provoking agent

Marked commitment present	*Provoking agent (n=303)* %	*NES (n=303)* %	*Onset (n=150)* %
Yes	50 (126/250)	22 (56/250)	21 (27/126)
No	45 (24/53) NS	47 (25/53) $P<0.001$	13 (3/24) NS

assessment of relevant plans. The resulting increase in the strength of the link between the provoking event and onset can thus be seen as empirical support for the theoretical basis on which the rules of the contextual threat ratings were devised. We were surprised, however, that further analysis did not reveal any patterning in terms of number or type of commitment and other key variables. The only association to emerge was for those without any instance of marked commitment, 18% (53/303) of the sample, who had double the rate of negative evaluation of self (Table VII). However, such a lack of commitment did not translate into a higher risk of depression; indeed, there was a tendency for those with no marked commitment to have, if anything, a lower risk of depression (Table VII). In fact, this result sums up our conclusions about C-events. They appear to reflect the fact that marked commitment increases the saliency of a loss and hence risk of depression. The fact that a C-event, by definition, cannot occur among those with no such commitments, and that these latter women, if anything, have a lower risk of depression in spite of having much more negative evaluation of self, supports this straightforward interpretation.

The interpretation of D-events is more complex. Although, as already noted, we have not included R-events stemming from role conflict in our current model, the association between them and matching D-events does appear to contribute to the understanding of the mechanism underlying D-events. However, this contribution becomes clearer if response in terms of hopelessness to the D-event is considered at the same time.

Hopelessness

In our general theory of depression, we have speculated about the importance of generalised hopelessness in response to any crisis, and that the presence of a vulnerability factor such as lack of a close confiding relationship serves to increase the probability of such a response (Brown & Harris, 1978). For the 110 women questioned in detail about their response to a particular severe event, only 18% reported complete lack of hope. Since the measure was based on material collected after any onset of depression, it is open to various kinds of inaccuracy and bias. However, it is of note that, among the 35 women with a D-event, marked hopelessness was highly related to a quite independent judgement made by the interviewer about the possibility of the difficulty being resolved—64% (9/14) among those with a matching difficulty with low chances of resolution compared with 20% (4/20) of the rest ($P<0.01$) (one not known). Such hopelessness was also low among those with a severe event but without a D-event (9% [7/77]). A provisional argument can therefore be made that women with marked difficulties are more likely to respond with hopelessness once any severe event arises linked to the difficulty. Although tentative, this interpretation is made more plausible by the fact that the difference in hopelessness between those with and without a D-event also holds for those *not* developing caseness of depression (Table VIII). (This is confirmed by logistic regression.)

TABLE VIII

Marked hopelessness in response to a provoking agent in terms of whether the woman was an onset case and had a D-event

D-events	*Onset case*	*Not onset case*	*Total*
	% marked hopelessness		
Yes	56 (9/16)	27 (4/17)	42 (13/33)
No	23 (3/13)	6 (4/64)	9 (7/77)
Total	41 (12/29)	10 (8/81)	18(20/110)[1]

[1] Two D-events and 18 non-D-events not known for 'hopelessness'.

The presence of either marked hopelessness or an R-event goes a good way to explaining the much higher rate of onset among those with a D-event: those with either hopelessness (5/6), matching role conflict (5/9) or both (2/4) had a higher risk of onset than the remaining women with a D-event (63% [12/19] *vs* 25% [4/16]; $P<0.05$. However, those with a D-event without marked hopelessness or matching role conflict still had a relatively high rate of onset, and for a satisfactory explanation it is probably necessary to take account of vulnerability as represented by negative evaluation of self. As might be expected, since all D-events were by definition linked to a long-term marked difficulty in key areas of a woman's life, they were also associated with negative evaluation of self (57% [20/35] of those with a D-event *vs* 32% [30/95] of the rest of the women with a severe event; $P<0.05$. Those with a C-event but no D-event had a rate of 34% [10/29]). (In fact this association reflects an underlying association between the presence of an ongoing marked difficulty of 6 months or more at first interview and negative evaluation of self—47% [35/75] *vs* 20% [46/228]; $P<0.001$.) When negative evaluation is taken into account together with marked hopelessness and matching role conflict, the particularly high rate of onset among those with a D-event disappears (59% [15/26] onset among those with one or the other *vs* 11% [1/9] of the remaining women with a D-event; $P<0.02$).

Discussion

This analysis has indicated that considerably more can be done, even in a cross-sectional survey, to increase the level of association between a severe event and onset of depression. Even if C-events involving prior commitment and R-events involving prior role conflict are not considered because they concern material collected at the first interview, differentiation in terms of risk of depression is still considerable. If we take into account the refinement of the severity rating, whether the severe event involves a loss and whether it is linked to an ongoing marked difficulty, there is a 15-fold difference between the two extreme risk categories (i.e. using the last column of Table V). Once matching commitment and negative evaluation of self are taken into account, the added precision is impressive (i.e. Table VI). It does appear possible to define a pattern of experience where the majority will quickly develop clinical depression. If such a group is formed by taking the presence of a severe event matching a prior difficulty (D-event) *or* an 'upper' loss event in the context of both negative evaluation *and* matching commitment (C-event), 63% (20/32) of all onsets of depression fall into this high-risk group, and as many as 51% (20/39) of the risk group develop depression (whole of the top row and first column of the second row in Table VI). If a somewhat less strict definition of high risk is taken—a D-event, or a severe event with 'upper' loss with either negative evaluation of self *or* matching commitment—then these proportions are 81% (26/32) and 43% (26/60) respectively (whole of the top row and the first three columns of the second row in Table VI).

Of course, negative evaluation is a vulnerability factor and cannot be seen strictly as part of the event. However, this analysis begins to threaten any tidy conceptual distinction between provoking agent and vulnerability factor and we will consider this in a later publication. However, we believe nonetheless that they can and should be measured separately, and ideally, as in this enquiry, at different points in time. Severe events linked to an ongoing difficulty (D-events) are particularly important here. They are quite highly associated with negative evaluation of self, as a result of the underlying association between marked long-term difficulties and negative evaluation of self. It seems reasonable to assume for the present that much of this association reflects the influence of the ongoing difficulty on self-esteem and we have presented evidence for this in another paper (Brown *et al*, 1986*b*). (In Table IV it was seen that the great majority of these difficulties had lasted over 2 years: the average length was 4.1 years.) If this is accepted, then a long-term difficulty will serve to reduce self-esteem and in time usher in the life event leading to onset. However, we have also seen that the association of D-events with negative evaluation of self provides only part of the explanation of their particularly high link with depression, and it is probably necessary to take into account other cognitive processes. Here we discussed the overlap of D-events with matching role conflict events (R-events) and also the tendency of women to respond to D-events with marked hopelessness. In his extraordinary story, *Albert Nobbs*, George Moore tells of the experiences of a woman who spent her life disguised as a waiter in a Dublin hotel. A crisis occurs in which she tells her story of deprivation and hardship to someone who discovers her secret: "I thought nobody would ever hear it, and I thought I should never cry again . . . It is much sadder than I thought it was, and if I had known how sad it was I shouldn't have been able to live through it". It is a common experience that great deprivation, hardship and disappointment can be shifted more or less permanently to some peripheral part of consciousness; and one role of life events can be to tell us something central about our lives that we have known in one sense all along. The role of matching difficulties and commitments indicates the importance of the loss of something upon which one has heavily staked a part of oneself and, furthermore, that one can lose again something essentially already lost.

The present study is an exploratory one and needs replication. However, all the main findings were the result of hypotheses formulated before the study began and all those involving measures made at follow-up were confirmed by an additional analysis of the anterior year data. As a whole, the findings of course underline the importance of social environment and cognitive factors in the aetiology of depression. They also offer some support for the conclusion of the earlier research in Camberwell that it is the meaning of *particular* events that tends to be crucial for depression and that, in so far as generalised hopelessness plays a role in the aetiology, it often stems from a highly particular set of circumstances.

Acknowledgements

The research in Islington was supported by the Medical Research Council. We are grateful and indebted to the women who took part in the interviewing and spoke to us at such length and also to the many general practitioners in the area who collaborated with us. We are indebted to our colleagues Tom J. Craig, Zsuzsanna Adler, Julia Brannan, Linda Bridge, Titus Davis, Jessica Meyer and Eileen Neilson who participated in the interviewing, to Laurie Letchford for work with the computer and to Joanna Brown for help with additional rating of the material.

Schizophrenia therapy: the importance of balance

Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets this critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.[1]

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,[2-5] and because injections need only be given every four weeks, patients hardly know they are being treated.

Piportil

DEPOT PIPOTHIAZINE PALMITATE

Piportil Depot Prescribing Information
Dosage: *(Adults)* Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg (1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, severe cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, depression, blurred vision, asthenia, impotence, dry mouth, nausea, amenorrhoea, galactorrhoea, hypotension, hyperhydrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08½ ampoules (PL0012/0117). **References:** 1. A SCHIZOPHRENIC.

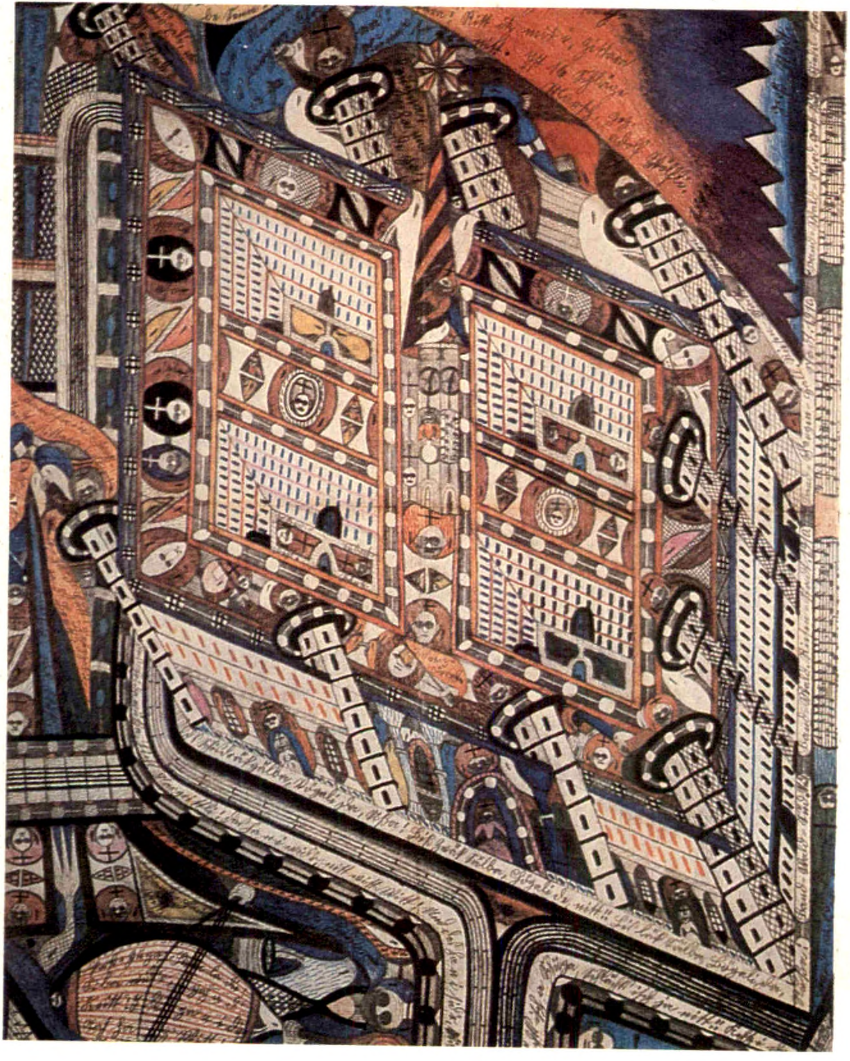
Adolf Wölfli spent 35 years in the Waldau Mental Hospital, Berne, suffering from schizophrenia. During that time he produced many drawings that have since gained widespread acclaim.

The picture below is one of a number that, we believe, give an insight into the schizophrenic mind and is reproduced with the kind permission of the Museum of Fine Art, Berne.



A SOLUTION.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol it has become widely established throughout the world as an effective antipsychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration following a single deep intramuscular injection.

Dosage is from 50–100mg in mild symptomatology whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation and a reduced requirement for antiparkinsonian medication, leaving him better able to participate in other forms of therapy.

100mg/ml

HALDOL*

haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

▼**Presentation:** Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses:** As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side-effects, precautions, contra-indications:** Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa, and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side Effects: In common with all neuroleptics, the following side effects may be observed: sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Rarely neuroleptic malignant syndrome has been reported. **Dosage:** Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. Dosage should be individually determined. As a guide: in mild symptomatology and in the elderly 50-100mg every 4 weeks; in moderate symptomatology 100-200mg every 4 weeks; in severe symptomatology 200-300mg or more every 4 weeks. **Product Licence No:** PL0242/0095, PL0242/0094 **Basic NHS Cost:** 100mg/ml: 1ml x 5 £24.00; 50mg/ml: 1ml x 5 £15.60 (correct at time of printing). Further information is available on request from **Janssen Pharmaceutical Limited**, Grove, Wantage, Oxon OX12 0DQ.

When depression is the source of anxiety...

PROTHIADEN

Dothiepin Hydrochloride B.P.

restores peace of mind

Differential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female patients will usually present with symptoms of both. The potential risks of an inappropriate choice of treatment for these patients can often be a cause for concern.

Prothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this concern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left untreated.

So, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well as that of your patients.

PRESCRIBING INFORMATION

Presentation: Prothiaden is Dothiepin Hydrochloride B.P. an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 75mg £4.00 as at 1st Nov. 1986. **Product Licence Numbers:** PL0014/5941, PL0014/0209. The Boots Company PLC, Nottingham, England. Further information available on request.

Prediction of Outcome in Depressive Illness by the Newcastle Diagnosis Scale

Its Relationship with the Unipolar/Bipolar and DSM-III Systems

M. W. P. CARNEY, E. H. REYNOLDS and B. F. SHEFFIELD

The Newcastle scores of a group of 64 and subsample of 52 severely depressed inpatients were not normally distributed. Evidence for discontinuity in these distributions was adduced from the contrast in outcome between the endogenous and neurotic patients thus defined, the endogenous consistently doing better than the neurotic group. The unipolar/bipolar system failed to predict different results for endogenous and neurotic patients unless unipolar was subdivided into endogenous and neurotic subgroups. The DSM-III criteria for major depression and melancholia failed to identify subgroups of differing prognoses.

The controversy between the exponents of the monist and dualist theories of the classification of depressive disorders was reignited by the studies of Kiloh & Garside (1963), Carney *et al* (1965) and Sandifer *et al* (1966) favouring the two-type thesis of depression. Their findings, however, were contested by Kendell (1968) and Post (1972). The argument continued, mainly in the correspondence columns of the *British Journal of Psychiatry* (e.g. Garside, 1973), until the mid-1970s when interest in it faded. The rating scale devised by Carney *et al* (1965)—the Newcastle Index—continues to be used, however, in making the distinction between endogenous and neurotic depressions (e.g. Checkley, 1978; Bech *et al*, 1980; Coppen *et al*, 1983; Carney, 1986). Much was made of the signficance of finding a unimodal or bimodal distribution of Newcastle scores for the monists' and dualists' cases respectively: Garside & Roth (1978) pointed out that a unimodal distribution does not exclude the possibility of at least two depressive populations and Kendell (1982) has recently emphasised that evidence of discontinuity in some independent correlate such as clinical outcome or the distribution of a biological marker like the dexamethasone suppression test (DST) would provide such evidence, even in the presence of a unimodal distribution of scores.

The findings of fresh studies, using the Newcastle Index (Davison *et al*, 1984; Zimmerman *et al* 1986a: Zimmerman *et al*, 1986b ('Iowa Group')) have revived interest in the issue. Though in each study the Newcastle distribution did not depart significantly from normal, and therefore failed to replicate the original Newcastle distributions (Carney *et al*, 1965; Carney & Sheffield, 1972), other evidence suggested that these two kinds of depression were not accounted for by differences in severity of illness alone.

The Iowa group applied the Newcastle Index to 159 depressed inpatients and found that endogenous depressives so-defined had a significantly higher rate of the DST non-suppression than Newcastle Index neurotic depressives (Zimmerman *et al*, 1986a). In 152 of these patients they showed that the morbid risk for alcoholism in endogenous depression was lower than that for neurotic depression (Zimmerman *et al*, 1986b). In both studies the relationship between the Newcastle scores and these variables was non-linear. Davidson *et al* (1984) studied the Index in 36 depressed patients: endogenous and non-endogenous patients thus defined responded differently to isocarboxazid.

This paper describes relationships between Newcastle scores, Hamilton scores and other measures of outcome found incidentally in the course of a series of trials of S-adenosyl methionine (SAM), a normal brain metabolite with antidepressant properties (Carney *et al*, 1983; Reynolds & Stramentinoli, 1983; Reynolds *et al*, 1984). This paper deals with patients admitted to a pilot trial and three admitted to a controlled comparison with amitriptyline (all treated with SAM) together with the first 46 entering the placebo-controlled trial of SAM.

TABLE I
Demographic data from the first 58 patients completing the SAM trials

		Age (years)	*Sex*		*Treatment*	*Group*
	n	*Mean ± s.d.*	*M*	*F*	*SAM*	*Placebo*
Endogenous	31	55.3 ± 18.6	14	17	18	13
Neurotic	27	53.6 ± 12.6	7	20	16	11

Method

The Newcastle scales were applied to depressed patients admitted successively on clinical grounds to Northwick Park and Kings College Hospitals. These patients were judged to be primary depressives, free of non-depressive disorders (epilepsy, drug and alcohol abuse, schizophrenia and organic brain states) who had scored at least 20 on the Hamilton Rating Scale (HRS). They all gave informed consent and underwent a 7-day drug-free 'wash-out' period before being admitted to one of the above trials. S-Adenosyl methionine or placebo were given daily intravenously to a total of 14 injections, each under identical conditions. Patients were assessed on admission to the trial on several rating scales, including the HRS; and on the 7th and 14th days on the HRS. A total of 64 patients (including 52 Northwick Park patients) were assessed for these trials. An arbitrary decision for logistical reasons was made to study further the first 46 patients to enter the double-blind trial, together with the 15 patients entering the other trials—61 in all. Of the 61 patients, 58 completed the 2-week trial period and the Hamilton data are complete and available in 52 of these. Patients scoring more than 5 on the Newcastle scale were classified as 'endogenous'; and 5 or less 'neurotic'. There were no significant differences between these two categories on age or sex distribution or the allocation of SAM or placebo (Table I). Neither did the pilot and double-blind trial patients differ on age and sex distributions.

Results

The distributions of the Newcastle scores of all 64 patients and the 52 Northwick Park patients assessed for the projects are shown in Figs 1 and 2 respectively (there were too few King's patients to be dealt with separately in this analysis). While the distribution for the whole group departs significantly from normality ($\chi^2 = 18.47$, d.f. $= 6$, $P < 0.01$), that of the Northwick Park subsample is more clearly bimodal ($\chi^2 = 28.7$; d.f. $= 6$: $P < 0.001$). Though these results, to a large extent, echo the original Newcastle findings, rigorous conclusions should not be based on them for reasons given below. However, when the mean falls in HRS for various values of Newcastle scores are compared (Table II) the series is clearly non-linear with an abrupt increase from 3–5 to 6–8, indicating discontinuity in the data. Moreover, though there are no significant differences between the initial mean HRS scores for 'endogenous' and 'neurotic' patients in both the total sample and the Northwick Park subsample, when the mean falls in HRS over the trial period in both groups are compared, there are significant differences, the 'endogenous' patients achieving the greater fall in each case (Table III). For the total sample this was 9,97 (endogenous) and 3.06 (neurotic) and for the Northwick Park patients, 10.59 and 2.13 respectively.

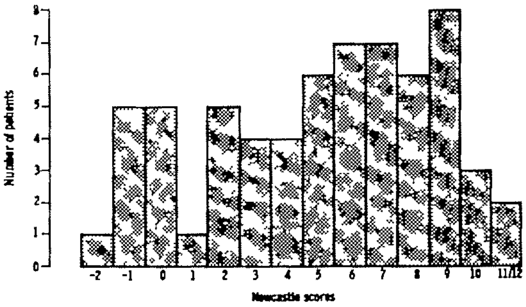

FIG. 1. Newcastle scores of 64 NPH and Kings patients

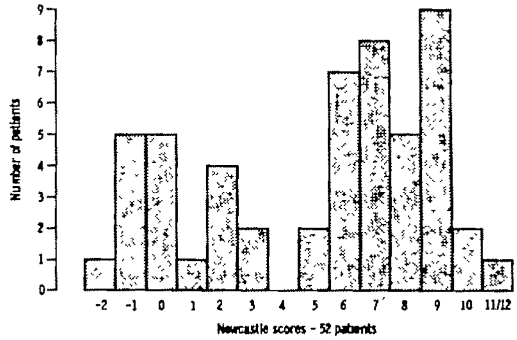

FIG. 2. Distribution of Newcastle scores: Northwick Park

We also examined the possibility that individual clinical features rather than the diagnosis endogenous depression was responsible for the difference in outcome between the depressive types. To do this we examined its relationship to the following subscales on the HRS; anxiety (psychic and somatic); insomnia (early, middle and terminal); delusions: weight loss (0,1 and 2); and agitation and retardation. None of the Hamilton subscales showed any significant association with a diagnosis of endogenous-neurotic depression as judged by Newcastle score and therefore could not have accounted for the difference between these groups.

TABLE II
Mean fall in HRS for various values of Newcastle Score: 58 patients

	'Neurotic'			*'Endogenous'*	
Newcastle score	<0	0–2	3–5	6–8	>8
No. of patients	6	9	12	20	11
Mean fall in HRS	1.2	2.9	2.9	9.7	5.6

TABLE III

Mean initial and mean falls in HRS scores for all 58 and 46 Northwick Park subsample patients (27 'endogenous' and 19 'neurotic') followed up for 2 weeks

			n	*Endogenous* (±*s.d.*)	*Neurotic* (±*s.d.*)	*t*	*P*
All patients	Mean initial	HRS	61	26.87±5.18	24.86±3.60	1.65	>0.05
	Mean fall in	HRS	58	9.97±8.72	3.06±6.15	3.32	<0.01
NPH patients	Mean initial	HRS	46	26.79±5.25	23.87±11.84	1.96	>0.05
	Mean fall in	HRS	46	10.59±8.67	2.13±5.32	3.63	<0.01

Very marked improvement

When those patients who had achieved 66% reduction in Hamilton's score are compared with those who had not achieved this reduction, eight of the 'endogenous' and no 'neurotics' were found to have achieved this standard of improvement. The difference is significant ($\chi^2 = 8.34$; d.f. = 1: $P<0.01$). Thus, 25% of those diagnosed 'endogenous' by the Newcastle score achieved this superior grade of improvement, whereas none of those categorised as 'neurotic' by the Newcastle did so.

Bipolar/unipolar classification

Northwick Park patients with whom there was historical evidence of one or more manic episodes of at least 2 weeks' duration each (these data were not available for the Kings College patients) were classified as 'bipolar' and those case histories which lacked such evidence, unipolar. The 46 patients for whom sufficient data were available to make this distinction comprised 12 bipolar and 34 unipolar patients, 17 of them with 'endogenous' Newcastle scores and 17 with 'neurotic' scores. The mean initial HRS scores of these groups (Table IV) did not differ—neither did the age, sex or SAM/placebo distributions—but the mean falls in HRS of both the bipolar and endogenous unipolar patients were significantly greater than that of the neurotic unipolar patients. Bipolar and endogenous unipolar groups, however, did not differ in this respect.

DSM-III classification

The DSM-III classification (DSM-III, 1980) specifies criteria for major depression of which bipolar psychosis and melancholia are subgroups. None of these definitions was entirely satisfactory for our design, as unlike ratings on the HRS and Newcastle scales, they are not quantifiable for the purposes of comparison or prognostic prediction. When we looked at the case histories of the above 46 Northwick Park Hospital depressives it was evident that they all satisfied the criteria for major depression. These comprise dysphoric mood or loss of pleasure continuously present for at least 2 weeks prior to assessment in the presence of four or more of the following: changes in appetite and weight; sleep disturbance; psychomotor retardation or agitation; loss of pleasure in usual activities including sexual interest; anergia; self-criticism or guilt; diminished ability to think or concentrate; ideas of suicide and death. By these criteria, all these patients were major depressives so that the diagnosis of major depression within the context of this subgroup did not further identify groups of contrasting prognoses.

We then looked at our patients in the light of DSM-III criteria for depression with melancholia. The discriminating criteria, in addition to other major depressive criteria, were at least three of the following: distinct quality of depressed mood; morning aggravation; early morning waking; psychomotor retardation and agitation; significant anorexia or weight loss: excessive or inappropriate guilt. There were 25 melancholic and 21 non-melancholic patients (Table V). They did not differ on mean initial HRS but both groups showed significant falls in HRS over the 14 days, the extent of these falls however not differing significantly ($t = 0.9$).

TABLE IV

Unipolar and bipolar patients: mean initial and mean fall in the HRS scores

		HRS score ± *s.d.*	
Type of patient	*n*	*Mean initial*	*Mean fall over trial period*
Bipolar	11	24.6±3.65	10.5±9.96
All unipolar	34	24.9±5.7	5.7±7.43
Unipolar endogenous	17	26.9±5.77	8.1±7.36
Unipolar neurotic	17	23.4±4.43	2.6±5.02

TABLE V
Mean initial and 14-day Hamilton's scores for melancholic and non-melancholic (DSM-III) patients completing 14 days' trial

	Number	*Mean HRS ± Standard deviation*		*Significance of fall*	
		Initial	*at 14 days*	*t*	*p*
Melancholia	25	26.9±4.35	19.6±11.08	3.00	<0.01
Non-melancholia	21	23.3±3.75	18.6±7.9	2.4	<0.05

Discussion

The investigation arose only incidentally out of a larger project—a series of trials of the anti-depressant efficacy of SAM. These were all severe, drug-free, primary depressives admitted for normal clinical reasons. It must be emphasised that the Newcastle scale was only one of the several administered on assessment for the trials before the results of treatment could have been predicted. Though a study of the distribution of Newcastle scores in depressed patients and its relationship to treatment outcome was not among the original purposes of the investigations, it early became apparent that the endogenous depressives were faring better than the non-endogenous patients so it was decided to investigate this aspect. For reasons quite beyond the original trial design, an arbitrary endpoint, short of the termination of the controlled trial, was selected and the data analysed after the completion of the controlled trial. This trial is now complete but all the data for all the trial patients have yet to be analysed. Nevertheless, because a study of the endogenous/neurotic dichotomy was not one of the original purposes of the investigation, the validity of the present result is thereby enhanced.

The endogenous and neurotic patients (as judged by Newcastle score) did not differ appreciably on our principal objective criterion of severity of depression—Hamilton's score. However, they did differ significantly on an independent variable, clinical outcome, patients with a Newcastle score of more than 5 being significantly better than those with a lower score. This finding was not accounted for by age, sex or treatment variations. The difference is so marked that the investigators have decided that a future trial should be confined to endogenous depression.

The evidence of the distribution curves, though not supporting the unitary view, does not constitute conclusive evidence for the binary thesis. The shapes of these curves depend upon several factors: the attitudes of the assessors, the populations being sampled and the method employed. Variations in these factors may have contributed to the different shapes of the curves from the Northwick Park subsample and the total sample, the former being clearly the more bimodal, and the latter doubtless being influenced by the characteristics of the King's patients. However, there was more than one assessor so that individual variations would have tended to cancel each other out: and the Northwick Park and King's catchment area populations differed in social class, structure and ethnic origin. Moreover, we were probably not looking at random samples of the general population, sources of potential bias being the mode of referral to hospital and the criteria of selection for the trials. Nevertheless, the difference in outcome between the endogenous and neurotic patients in both samples was equally marked and for reasons already given the evidence of distribution curves should not be awarded decisive importance in the context of this argument. It should not seriously detract from the case for the binary view, particularly in the light of the significant associations between diagnosis and outcome. Moreover, the Newcastle scale was only one of several rating scales applied on admission to the trial after a drug-free week, before injections were started or the outcome was predictable and the Registrars who carried out these investigations were not involved in the monist-dualist controversy. It was unlikely, therefore, that these ratings were influenced by preconceived nosological ideas on their part. Thus, the shape of these curves does not support a unitary explanation but to a great extent they confirm the original Newcastle findings (Carney *et al*, 1965). Firm evidence of a meaningful discontinuity (Kendell, 1982) in this patient population was provided by the abrupt break in mean reductions in HRS scores on either side of Newcastle score 5, the patients on the 'endogenous' (>5) side of this break faring significantly better than those on the non-endogenous side. Thus, the Newcastle scores constituted a non-linear series linked with an independent criterion, clinical outcome.

The whole question of prediction of outcome is of considerable interest. In the original paper (Carney *et al*, 1965) it was shown that outcome could be more accurately predicted by a set of features specifically related to ECT response than by diagnosis, and an ECT prediction index was based on these. The question arises—could not this device have been applied in the present work? It was not included in the trial design for these studies because at that time there seemed no good reason for doing so. Moreover, the wisdom of attempting to base conclusions about diagnosis and classification on the response to a particular treatment is basically unsound (Carney *et al*, 1965). Neither can it be automatically assumed that weighted features predictive of response to ECT will be the same for response to SAM. Finally, it was practically not possible to introduce the ECT Prediction Index at a late stage in the present work because it comprises a different set of 10 features with different weights from those of the diagnosis index. In respect of only two features—'anxiety' and 'weight loss'—do these inventories overlap. Both the other schemes of classification we examined depend on different sources of variation, the unipolar-bipolar on polarity, and DSM-III, a combination of severity of depression ('major depression') and criteria for distinguishing endogenous from non-endogenous depression (melancholia and non-melancholia). The unipolar–bipolar data indicate that there was only a modest difference between bipolar and all unipolar patients. However, when the HRS results for the bipolar and neurotic unipolar patients were compared there was a radical difference as there was between endogenous unipolar and neurotic unipolar patients.

However, when bipolar and endogenous unipolar patients were compared, there was no significant difference. Roth & Barnes (1981) have already stressed that in assessing the results of treatment in depression it is important to distinguish between endogenous and neurotic varieties of unipolar patient. Failure to make this distinction may result in valuable differences being submerged and possibly false conclusions being drawn.

The DSM system of classification is enjoying widespread popularity in the United States, perhaps not so enthusiastically shared by European psychiatrists. By DSM-III criteria all our patients would have been classified as major depressives. Subdividing into melancholics and non-melancholics however was not associated with differences in outcome so that the use of this system in this material would not have better predicted the outcome. Meaningful results from many drug trials will not be forthcoming until the endogenous–neurotic source of variation is taken into account (Montgomery, 1981). This is not to say that varieties of depressive disorder other than these two may not eventually be established, but the endogenous subgroup, in particular, is particularly stable and shows up consistently in other studies using various methods of analysis, especially cluster analysis (Paykel, 1971, 1981).

Factor Study of a Psychiatric Child Rating Scale
Based on Ratings Made by Clinicians on Child and Adolescent Clinic Attenders

G. THORLEY

Symptom rating sheets completed by psychiatrists over a 9-year period on 2602 intellectually normal child and adolescent clinic attenders were subjected to factor analysis (principal components). Two types of factor sets were derived, one for younger subjects (3–11 years) and another for older subjects (12–18). Both had three factors in common: conduct disturbance, relationship problems and emotionality, but differed on the fourth – developmental immaturity for the younger group, depression for the older. A factor solution was also derived for the whole clinic sample with three scales: conduct, emotionality and immaturity. Both types of factor solutions were subjected to MANOVA for age and sex effects, both of which proved to be of significant influence. Good correspondence was found between the symptom factors identified and conceptually similar clinical diagnoses.

Patterns of association between psychological symptoms have been investigated widely and have provided a basis for many classification schemes, diagnostic instruments and clinical rating scales for the assessment of psychopathological disturbance in children and adolescents. Such work has primarily involved the multivariate analysis of data and recent reviews (Achenbach, 1978; Quay, 1979) have suggested that certain dimensions appear consistently and are characterised by aggressive, delinquent, hyperactive, schizoid, anxious, depressed and withdrawn symptom domains (Achenbach, 1978).

These findings are particularly interesting given the heterogeneous nature of the studies involved, using subjects of different age-ranges, sex ratios and clinical groupings as well as employing different types of observer and assessment method. Although these broad findings are of value, several limitations are evident. In particular, differences which may exist between sexes and different age-ranges are obscured and the few studies which have investigated this (Jenkins & Glickman, 1946; Arnold & Smeltzer, 1974; Achenbach, 1978; Soli *et al*, 1981) do indicate that such effects are indeed present. In addition, most studies have employed parents or teachers to make ratings on subjects and only two studies have employed health service professionals to make direct clinical ratings on clinic attenders (Collins *et al*, 1962; Borgatta & Fanshel 1965).

If such analyses are to provide a sound basis for psychiatric diagnostic or classificatory schemes, it would seem important to use symptom ratings made on psychiatric clinic attenders by experienced clinicians, for ratings made by such groups as teachers, though widely employed (Thorley, 1983), have been shown in normal subjects to lack sensitivity, especially to emotional pathology (Green *et al*, 1980). Perhaps most important, as Achenbach (1978) has pointed out, is the lack of clinical validity for the symptom dimensions revealed by multivariate analysis of rating scale data, although a study by Neuchterlein *et al* (1981) has made a notable attempt to rectify this deficiency.

For these reasons, the present study was designed to provide a factor analysis of contemporary clinical symptom ratings made by psychiatrists on child and adolescent clinic attenders. Also, a systematic analysis of age and sex differences has been conducted as well as an attempt made to provide clinical support for the symptom factors by relating them to formal psychiatric diagnoses made on the same subjects.

A more limited aim of the study was simply to provide clinicians and researchers with a strategy to reduce the symptom data collected by the use of the clinical data sheets developed by the Bethlem Royal and Maudsley Hospitals to a more manageable and yet robust form.

Method

All intellectually normal (IQ > 70) child and adolescent clinic attenders at the Maudsley and Bethlem Royal Hospitals over

TABLE I

Symptom items rated by clinicians

Emotional symptoms

1. Abnormal suspiciousness or 'sensitivity'.
2. Morbid anxiety, worrying or panic.
3. Morbid depression, sadness, unhappiness, tearfulness.
4. Situation- or object-specific fears or phobias.
5. Ruminations, obsessions, rituals or compulsions (do not include faddiness, rigidity or other obsessive traits).
6. Suicidal ideas, attempt or threat.
7. Hypochondriasis.
8. Morbid irritability, screaming, tempers, breath-holding attacks.
9. School refusal, or phobia or crying on arrival at school.
10. Abnormally elevated mood (including hypomania).
11. Depersonalisation or derealisation.
12. 'Conversion' hysterical symptoms (do not include histrionic behaviour).

Somatic

13. Disturbance of eating (pica, refusal, abnormal faddiness etc.).
14. Disturbance of sleeping (insomnia, nightmares, sleepwalking etc.).
15. Pains of mental origin (headache, backache, abdominal pains, nausea, leg pains).
16. Encopresis or faecal soiling.
17. Enuresis.
18. Any non-epileptic disturbance of consciousness (fainting etc.).

Disturbance of relationships

19. Overt disturbance of child–mother relationship (including hostility, dependency etc.).
20. Overt disturbance of child–father relationship.
21. Overt disturbance of relationship with other adults (e.g. school teacher).
22. Overt disturbance of patient–sib relationship (including morbid rivalry or jealousy).
23. Overt disturbance of relationships with other children (including isolation, failure to make friends etc.).
24. Autism, social withdrawal, aloofness or detachment (not necessarily psychotic).
25. Socially disinhibited.

Speech and language

26. Disorder of rhythm (e.g. stuttering).
27. Disorder of articulation.
28. Disorder of comprehension of spoken language.
29. Disorder of production of spoken language (including simple retardation of language development).
30. Elective mutism.

Motor

31. Tics.
32. Other abnormal repetitive movement (whirling, flapping, twisting of hands, etc.).
33. Clumsiness or poor coordination.
34. Restlessness or fidgetiness.
35. Gross overactivity.
36. Hypoactivity.

Habitual manipulations

37. Thumb-sucking, tongue-sucking, rocking, masturbation, nailbiting, scratching, head-banging etc.

Antisocial behaviour or disorders of conduct

38. Disobedience (active or passive) or lying.
39. Stealing.
40. Destructiveness or malicious damage.
41. Fire-setting.
42. Truancy or staying out late.
43. Running or wandering away from home.
44. Sexual misbehaviour (assault, exposure etc.).
45. Fighting, bullying, aggression etc.
46. Violent assault (stabbing or use of other weapon or corrosives, severe physical attack etc.).
47. Taking drugs.
48. Other antisocial behaviour (raising fire alarms etc.).

Other

49. Disorder of sex role, sex object or gender identity (cross-dressing, abnormal feminine behaviour in boys, homosexual orientation etc.).
50. Hallucinations, delusions, ideas of reference or morbid persecutory ideas.

a 9-year period (1973–1981) formed the subject group ($n = 2602$). Clinical information was recorded by therapeutically involved psychiatrists within 2 weeks of admittance. This data gathering and storage system has been described in detail elsewhere (Thorley, 1982) but the principal features of it are that the clinician records the clinical diagnosis (ICD 9) and other elements on a multi-axial scheme (Rutter *et al*, 1979) together with Likert-type ratings labelled 'absent', 'minimal or dubious' and 'definitely present' (scored 0, 1 and 2) on 50 symptom items (see Table I). Other details recorded, but not used in the present study, include family, demographic and referral details. Of some importance is that no particular hypothesis is under consideration at the time these ratings are made. In fact, the system is operated routinely in conjunction with the recording of casenote information. The symptom ratings made are each intended to record a global clinical judgement, based on information from all sources, relating to the previous 12 months' functioning. In practice, the data sheets are completed by a very large number of clinicians, the majority being registrars who spend a 6-month period in the Children's Department. The symptom items used have been selected in an evolutionary manner over several decades of operating such a system to satisfy clinical experiences and research requirements and are set out on the rating sheets under the following headings: emotional symptoms, somatic, disturbance of relationships, speech and language, motor, habitual manipulations, antisocial behaviour, and other. This clinical information is stored on computer for convenient and rapid access.

The analyses were conducted with certain criteria and objectives in mind. The overall aim of the study was to produce clinically meaningful and robust (generalisable) factor scales. As a first step, to limit the error variance, all symptom items which had been responded to in less than 10% and in more than 90% of cases were excluded from the analysis. Factors were then extracted using a principal components analysis, but some symptom items in which there were a significant amount of missing data (e.g. relationship with siblings, child–father relationship) were excluded from analysis. However, other information relating to the same cases was retained and used appropriately. Each analysis produced a large number of factors: 34 for an analysis of the entire clinic population, 29 for clinic subjects under 11 years of age and 21 for subjects aged 12 years and over. However, most of these factors consisted of a single symptom item or weak loadings on several. To reduce this number, the factors were rotated orthogonally by the varimax method. The initial criterion for retention of the rotated factors was an eigenvalue of 1.0. If this failed to produce a scale of four symptom items or more with factor weights of 0.30 or better, the number of factors retained for rotation was reduced still further until an optimal factor set was found. The objective of this method was to avoid a second-order analysis of factors but instead to aim for a parsimonious and robust selection at the outset. Choosing an orthogonal rotation method in factor analysis is to make certain assumptions about the underlying pattern of the data. This method was chosen because discrete dimensions of symptoms were expected on the basis of previous work with this type of data (e.g. Achenbach, 1978; Miller, 1967); however, all analyses were repeated using oblique rotation which resulted in factor groupings that were substantially similar. Therefore, there was no reason to abandon the varimax (orthogonal) solution.

Methodological issues

There are particular problems of reliability and validity which need to be considered in a study of this type. The reliability of the clinical ratings are of particular concern because they are made by a constantly changing population of clinicians, usually registrars with, in all probability, differing degrees of accuracy. Although some training is given in the completion of the clinical data sheets, it is not possible to be sure that the judgement of one rater is comparable with that of another because consistency checks are not carried out routinely. This particular type of unreliability can usually be assessed by tests of inter-rater reliability. However, this is impractical to do on the present data and requires a prospective study which is beyond the scale of this present project. If inter-rater agreement *is* poor, it is likely to result in substantial levels of error variance and make the extrapolation of robust factors difficult to achieve. If meaningful factors fail to emerge, this may well be one explanation.

A second problem of reliability concerns the use of Likert-type ratings, which are ordinal rather than of interval quality. This affects the underlying assumptions of factor analytical techniques which require variables of the latter type. This requirement is often disregarded in practice, but if inferences are to be made of other clinic populations and of the relationship between symptoms in general, it is important that this possible source of error be investigated. To accomplish this, a series of sensitivity analyses were carried out on each of the derived factor solutions. The object was to see if the factors obtained were influenced unduly by the arithmetical nature of the variables rather than by their content.

A limited look at the validity of the symptom factors obtained was made possible by examining whether individual scores computed from each factor have some relationship to the eventual clinical diagnosis given by each clinician — in other words, whether the factor scores have the power to discriminate well between diagnostic categories.

Results

The analyses were carried out in several stages and are reported in sequential order.

Factor analysis of subjects divided into different age and sex groupings

For this procedure subjects were divided into four subgroups: 5–11-year old boys ($n = 703$, mean age 8.4 years, s.d. = 1.9); 5–11-year old girls ($n = 335$, mean age 8.6 years, s.d. = 1.9) and 12–18-year old girls ($n = 691$, mean age 14.0 years, s.d. = 1.3). The factor sets for each of the subgroups

TABLE II

Factor analysis of clinic symptom data in two subpopulations: younger subjects (5–11) and older subjects (12–18)

Factor labels	*Symptom item numbers and factor weights*	*% common variance*
5–11-year old boys and girls		
I. Conduct	38(0.58), 39(0.57), 40(0.51), 42(0.54), 43(0.55), 45(0.41)	45.4
II. Relationships	8(0.32), 19(0.43), 20(0.42), 21(0.56), 22(0.50), 23(0.58)	26.3
III. Emotionality	1(0.38), 2(0.72), 3(0.40), 4(0.50), 9(0.47), 13(0.32), 14(0.38), 15(0.33)	18.1
IV. Developmental immaturity	25(0.53), 27(0.31), 33(0.48), 34(0.66), 35(0.61)	10.3
12–18-year old boys and girls		
I. Relationships	1(0.30), 8(0.42), 19(0.44), 20(0.43), 21(0.54), 22(0.48), 23(0.57), 25(0.30), 40(0.38), 45(0.42)	42.0
II. Conduct	38(0.59), 39(0.55), 42(0.62), 43(0.43)	35.1
III. Emotionality	2(0.53), 4(0.51), 7(0.53), 9(0.46), 15(0.48)	12.7
IV. Depression	3(0.65), 6(0.60), 14(0.43), 13(0.30)	10.2

were generally similar. Thus, in all groups factors of conduct disturbance and emotionality appeared, accounting for between 53 and 85% of the total common variance (after rotation). For both of the male groups, factors reflecting disturbance of relationships were present (younger = 19.5% of variance; older = 37.7% of variance), but the same symptom items, though not forming a distinct factor, were present in the conduct disturbance factors of both female groups. A factor consisting of overactivity and developmentally related items appeared quite strongly for younger boys (11.2% of variance) and younger girls (15.1% of variance), not at all for older girls and weakly for older boys (9.1% of variance). Finally, items suggesting depression appeared as a strong factor for older girls but were contained in the emotionality factor for older boys.

A consideration of these patterns resulted in the decision to reduce the subgroups to just two, younger subjects and older ones (5–11 years and 12–18 years). The items and factors which emerged over the four subgroups suggested that differences between sexes were not as important as those between age-groups, for the chief differences lay in the presence of depression-related items in older subjects, contrasting with what might be called developmental immaturity-type items in younger subjects (overactivity, fidgetiness, social disinhibition, disorder of articulation etc.).

Factor analysis of subjects divided into older and younger age bands

The results of this are presented in Table II and show four factors emerging for each of the age-groups, labelled for the younger subjects, 'conduct disturbance', 'disturbance of relationships', 'emotionality' and 'developmental immaturity'. For the older subjects, the same factors occur except for 'developmental immaturity' which is replaced by one of 'depression'.

These two sets of factors seem the most useful for clinical and research use, providing the age-ranges of subjects is similar. However, because it seems that both factor sets have much in common and also because subjects in research do not always come conveniently in similarly convenient age-ranges, there seemed some justification in attempting to fit the whole clinical population to a single set of factors, even if these were fewer in number.

Factor analysis of the entire clinic population

Using 2602 subjects, the analysis produced three distinct factors labelled 'conduct disturbance', 'emotionality' and 'developmental immaturity', each accounting for 42.0, 33.9 and 24.1% of the common variance, and containing 12, 11 and 7 symptom items respectively (Table III).

Correlations between factor scores

Correlation analyses were carried out on the three factor structure for the whole clinic population and also on each of the four factor sets for the two clinic groups subdivided by age. The results are presented in Table IV and, in general, confirm the statistical independence of the factors. Factor scores were computed for each case simply by summing items which had the highest weights on each factor. The highest intercorrelation for the factor set of the youngest age-band subjects was between the conduct and relationship factors (0.32); the next, a negative one between conduct and emotionality of −0.24, then one of 0.20 between relationships and developmental immaturity with the other correlations being at a lower level of association.

For the older age-band children, the strongest association of factors was of 0.37 between conduct and relationships followed by one of 0.36 between depression and emotionality. The other correlations were of a much lower order.

Finally, the three-factor structure for both age-bands combined had inter-factor correlations of a very low order. The highest, 0.18, was between developmental immaturity and conduct, whilst those between conduct and anxiety, anxiety and developmental immaturity were 0.

It is perhaps worth pointing out that, with the very large subject numbers involved in these correlation analyses, though reaching statistical significance, these weak correlations are probably clinically irrelevant.

Sensitivity analyses

When the factor structures had been obtained, the process was repeated, but this time the values of the symptom ratings were changed. The original rating values of 0, 1 and 2 were recoded to 0, 1 and 10 respectively and again to 0, 9 and 10 respectively. Each time the data were recorded in this way, repeats of the factor analyses were performed. Thus, a replication of the factor structures of (a) the entire clinic population, (b) the 5–11 year age-group and (c) the 12–18 year age-group was carried out.

Despite the gross distortion of the symptom rating values, the results of these procedures were that the original factor structures were replicated very closely with only minor variations being apparent. Therefore some confidence may be had in the factor structures reported, even though the symptom rating data was obtained from Likert-type ratings and thus did not conform to the usual assumptions of factor analysis. This stability is quite likely to be a consequence of the large number of subjects employed in this study.

Relationship of the symptom factor scales to diagnostic categories

This was carried out on the three factor scales derived from the whole clinic population and the hypothesis is that subjects diagnosed 'conduct disorder' should have higher scores on the conduct disturbance factor than either subjects diagnosed 'emotional disorder' or 'hyperkinetic syndrome'. In a similar way, subjects diagnosed 'emotional disorder' should have scores on the emotionality factor that significantly exceed those of the other two diagnostic groups. The same comparisons should also hold true for the 'hyperkinetic syndrome' subjects on the developmental immaturity factor scale.

The outcome of the comparisons (Table V) using one-way analysis of variance and Scheffe's *post-hoc* comparisons (0.10 α) supported the hypothesis without exception.

Age and sex trends

Factor set for younger subjects

Two-way analysis of variance was conducted to explore the effects of age (between the age-bands 5–6, 7–8, 9–10 and 11) and sex. The results are set out in Table VI.

Explained	428.2	7	61.2	14.2	0.001
Residual	7567.0	1757	4.3		

Conduct factor scale. Highly significant age and sex effects were found. Mean scores generally increased with age for both boys, particularly at age 11, but girls in every age-category returned lower mean scores.

Social relationships factor scale. No significant age, sex or interactive effects were found. The mean scores of both boys and girls were remarkably similar and were constant throughout all age-bands.

Emotionality factor scale. Highly significant age and sex effects but no interactive effects were found. Scores for boys and girls increased with age and in every age-band the mean scores of girls exceeded those of boys. The mean scores for both sexes increased sharply at age 11.

Developmental immaturity factor scale. Highly significant age and sex effects were found but no interactive ones. Mean scores for both sexes declined quite sharply with increasing age in every age-band. The mean scores for girls were considerably lower.

Factor set for older subjects

Similar analyses were carried out on the factor scales appropriate for subjects over 11 years of age. Two age-bands were employed: 12–13 years and 14–18 years. Results of the analysis of variance are set out in Table VIII.

Relationship factor scale. For this, as with the similarly named scale for younger subjects, no main or interactive effects were found. The mean scores for both boys and girls over the period of adolescence remained fairly constant.

Conduct factor scale. Moderately significant effects for age and sex were found but none for interaction. The mean scores for girls on both age bands were slightly lower and for both sexes the mean scores fell with increasing age.

Emotionality factor. Significant effects for sex but not for age or interaction were found. The mean scores for both age-bands were similar but were moderately elevated in both age categories for girls.

Depression factor. Highly significant age, sex and interactive effects were found. Mean scores for both girls and boys increased during the adolescent period but were notably higher for girls.

Factor set for all subjects

For each of the three factor scales, significant age and sex effects were found and, in addition, an interactive one on the developmental immaturity factor. Complete data are presented in Table VIII, in which mean values are given for the age- and sex-bands.

Conduct factor scale. Mean scores for both girls and boys increased with age and, in every age-band, were higher for boys.

Emotionality factor scale. Mean scores for both sexes increased with age quite consistently but, in contrast to the conduct factor scale, mean scores in every age-band were higher for girls.

Developmental immaturity factor scale. Mean scores generally declined with age and were lower in all categories for girls.

Summary of Results

Initial factoring of four subgroups, 5–11-year old girls and boys and 12–18 year old girls and boys revealed a factor pattern different essentially between age-groups rather than sexes. Two factor sets were then produced, each of four factors for the younger (conduct, relationships, emotionality and developmental immaturity) and older (relationships, conduct, emotionality and depression) subgroups. Nearly all of the factor scales revealed significant age and sex effects except for the social relationships scales for both the older and younger subjects, which showed neither, and the emotionality scale for the older subjects, which only showed a sex effect. Interactive effects were found on the depression (older subjects) and developmental (all subjects) factor scales.

Discussion

The results of the symptom factor analysis for both the younger (5–11 years) and older (12–18 years) clinic attenders are interesting in that, although factors labelled 'conduct', 'depression' and 'emotionality' are commonly found in other studies (Achenbach, 1978), ones labelled 'developmental immaturity' and 'social relationships' are not.

The developmental factor found in the younger group comprises symptoms reflecting overactive, socially disinhibited behaviour with poor coordination, speech and language delay. The factor is interesting in that it contains one of the central symptom features of hyperactive disorder. In reviewing factor studies of symptom data, Quay (1979) concluded that there was little evidence for a separate factor of hyperactivity as distinct from one of conduct disturbance and, indeed, in this study it seems likely that, if it were not for the presence of developmentally related items such as speech, language and motor dysfunctioning, it is doubtful whether the items related to hyperactivity would have remained independent of the conduct disturbance dimension. In conceptual terms this association of symptoms suggestive of developmental immaturity with those of hyperactivity is of interest and may explain why in some studies it emerges as a distinct dimension and in others it does not. Zukow *et al* (1978) confirmed the importance of this aspect of hyperactivity when, in attempting to devise a rating scale that would distinguish hyperactive from normal children, they found three major factors for a parent scale and two for a teacher scale. One factor which was common to both scales was one of motor coordination in which, interestingly, there was an item reflecting speech difficulties. In addition, Thorley (1984) found that disorder of articulation was one of the symptoms which distinguished the hyperkinetic syndrome children (ICD 9 diagnosis) from those with conduct disorder, although no differences in gross brain pathology were detected between the two groups. More broadly, Safer & Allen (1976) documented many studies in which numerous developmental features were associated with hyperactivity. These associations may thus explain why a separate factor with a hyperactivity-related item appeared in this, but less frequently in many other symptom factor studies.

The second factor of particular interest which appears in this study for both age-bands is the factor reflecting a disturbance of social relationships. This is satisfying from a conceptual and clinical viewpoint, since this type of disturbance, neglected in diagnostic schemes, seems to have important predictive value, as demonstrated in several studies (Robbins, 1966; Roff & Sells, 1968; Roff, 1969), and can be viewed as one of the more promising clinical predictors of outcome in adolescence and adulthood (Kohlberg *et al*, 1972).

The emergence of the factors of social relationships and developmental immaturity in this study and not others can be explained in part by the unique role that a clinican rather than a parent or teacher occupies. Symptom judgements about developmental pathology are difficult for parents or teachers to make and the clinician is in a uniquely advantageous position to assess disturbance of social functioning, because a judgement based on several sources of information can be employed in contrast to the narrower observational range of teachers or parents. Since all but two of the major symptom factor studies have employed respondents other than clinicians, it may not be too surprising that these factors have not emerged. Of course, an alternative explanation is that these factors are simply the result of a 'halo' effect: an artifact of certain clinical perceptions in which symptoms are recorded as being associated in a way that is not a true reflection of the real situation.

A further point of interest arising from the factor structures for the two broad age-bands is the appearance of a factor of depressive symptoms in adolescence. Mean scores on the emotionality factor scale for 5–11-year olds were higher for girls and increased with age. In adolescence, however, scores on the similarly labelled factor were more even between the sexes and constant over time. What changes is that a factor of depression appears, and on it girls score substantially higher, with their mean scores rising throughout the adolescent period. The processes involved are not clear. It could be that in some cases, diffuse emotional symptoms in childhood, particularly in girls, manifest themselves later as a depressive disorder or, perhaps in the postpubertal years, depressive symptoms arise without such precursors. Much of the longitudinal work has been concerned with prediction from childhood to adulthood (Kohlberg *et al*, 1972), but it would be valuable to know more of the pre-adult processes of emotional psychopathology.

An intriguing finding in the factor set relating to the younger (5–11 years) subjects is that, on the conduct and emotionality factor scales, the mean scores for both boys and girls rise quite strongly at 11 years of age. It is not clear why this should occur. Stress associated with change of school is perhaps an obvious factor, but clearly there could be others; ranging from intrapsychic processes (e.g. changes in ego development) to factors associated with the onset of puberty and to psychosocial disturbances (e.g. moving home, which many families choose to do in the school changeover period). Again, the topic seems worthy of investigation.

Reassuringly for the study as a whole, it does seem that the scales derived from the data sheets have some internal consistency and concurrent validity. Scores on the conduct scale distinguish between children diagnosed conduct disordered (ICD 9) and those diagnosed as emotional or hyperkinetic disorder. Similarly, scores on the emotionality scale distinguish those diagnosed emotional disorder (ICD 9) and each of the other two diagnostic groups, whilst scores on the developmental immaturity scale distinguish between those with a diagnosis of hyperkinetic syndrome and those with emotional or conduct disorder.

Finally, one of the most significant findings of this study is the importance of age and sex effects. Significant age effects are present in all three factor solutions on all scales except for that of 'social relationships'. This supports the findings of the few studies that have investigated such effects (Jenkins & Glickman, 1946; Arnold & Smeltzer, 1974; Achenbach, 1978; Soli *et al*, 1981) and taken together suggest that, in order to be useful, clinical rating scales require normative data along age-bands.

The importance of gender is also demonstrated. It has been suggested by Stewart *et al* (1981) that female clinic attenders may have specific syndromes (other than anorexia nervosa) unique to their sex. A study by these authors of 41 female inpatients found a weak suggestion of an elevation of somatic complaints in girls which may be attributed to hysteria. No evidence, at least in terms of broad symptom dimensions, was found in this present study to support this or any other qualitative difference between the sexes: the factor solution for both produced similar results. However, this is undisputedly influenced by the range of items put into the factor analysis. Where more items are included, the emergence of distinct sex-related factor structures is more likely (e.g. Soli *et al*, 1981). However, important quantitative differences are present. The three-factor solution for all age-groups showed that boys return higher mean scores in every age-band on the conduct disturbance scale. This pattern was not unexpected given the findings of several studies (e.g. Chazan & Jackson, 1971; Shepherd *et al*, 1971) which have demonstrated that boys more commonly than girls show oppositional and antisocial behaviour. Rutter *et al* (1970) also revealed from the Isle of Wight survey data that neurotic problems were much more common in girls. This is also supported by the gender differences on the emotionality factor scale where, on every age-band, girls returned higher mean scores than boys. On the third factor, developmental immaturity, boys returned higher mean scores on every age-band but, unlike the conduct or emotionality mean scores, the scores for both boys and girls decreased with age. This may be a true phenomenon—that such pathology decreases over time—or it may simply reflect a bias towards referral at an earlier rather than a later age. The finding of important effects for both age and sex as intervening variables suggest that clinical rating scales should be constructed within clearly defined age-ranges and that normative data should be available for both age- and sex-bands. From this aspect, the approach of Achenbach (1978) in constructing standardised scales for different age ranges and sex compositions seems justified.

In conclusion, the results seem to underline the potential value of this type of rating scale in which clinicians draw information from as many informants as possible by interview and perhaps questionnaires, and then make symptom ratings as a precursor to a diagnostic decision. Clearly, this is a conceptually different instrument than the psychiatric rating scale, a number of which are now available (e.g. Rutter & Graham, 1968; Kestenbaum & Bird, 1978; Hodges *et al*, 1981) but which are designed to collect information from the psychiatric interview alone. Since agreement between information from this source and that provided in a similar way by parents using similar scales is often poor (Reich *et al*, 1982), it is often difficult to quantify the process which eventually leads to a clinical diagnosis being given. The symptom rating scale of the Maudsley and Bethlem Royal Hospitals may be of value in research by providing symptom information more closely allied to the diagnostic decision than single source scales are able to do. From this point of view, and also as an integral part of a clinical data record system (Thorley, 1982), the symptom rating scales seem to have some value.

The Relative Stability of Positive and Negative Features in Chronic Schizophrenia

E. C. JOHNSTONE, D. G. C. OWENS, C. D. FRITH and T. J. CROW

The mental states of 92 inpatients with chronic schizophrenia were assessed on two occasions 4 years apart. The relationship between the two ratings was examined in the 84 patients who were either consistently on or consistently off neuroleptics. Negative features were more stable than positive, but were not irreversible. Every feature examined was shown to resolve in some cases.

It has become customary to classify the typical abnormalities of the mental state of schizophrenic patients into positive and negative features, with reference to behavioural excesses and deficits; positive features are pathological by their presence and negative features represent the loss of some normal function. The relationship between positive and negative features may not be simple (Wing, 1978) but the following generalisations have some support. Positive features are characteristic of earlier and negative of later phases of the illness (Pfohl & Winokur, 1982a). The effects of drugs upon positive features are greater than those upon negative features. Thus neuroleptics produce more marked improvement (Johnstone *et al*, 1978; Angrist *et al*, 1980) and amphetamine more marked exacerbation (Angrist *et al*, 1980) of positive than of negative features. Positive features have been said to be relatively variable and negative features relatively fixed (Ovchinnikov, 1968; Sneznevsky, 1968). There is evidence that the clinical (e.g. behavioural and neurological) correlates of the two groups of abnormalities are not the same (Owens & Johnstone, 1980). On the basis of such findings it is suggested that although manifestations of the same disease, these features may result from different biological processes (Crow, 1980) with that underlying the positive features being potentially reversible and that underlying negative features irreversible. The latter proposition finds some support in the fact that while clinical correlates of the cerebral ventricular enlargement sometimes found in schizophrenia are not constant, those that do occur have tended to concern abnormalities associated with negative rather than positive features. Although the question of the reversibility/stability of positive and negative features has assumed theoretical as well as practical interest (Crow, 1980) the progress, over a period of time, of positive and negative features has received little formal study. In general it is difficult to separate the question of reversibility/stability from that of responsivity to treatment, either in terms of neuroleptics or changing social factors. Negative features can be affected to some extent by social factors (Wing & Brown, 1970) although once established some impairment is likely to persist even in the most satisfactory social environment (Wing, 1978). The present study examines the reversibility/stability of positive and negative features over a 4-year period in a group of schizophrenic patients in a constant hospital environment, some of whom were and some of whom were not, receiving neuroleptic drugs throughout the period of investigation.

Method

The subjects of this study were part of a large cohort of patients who had participated in an earlier investigation (Owens & Johnstone, 1980) of schizophrenic patients all of whom fulfilled the St Louis (Feighner *et al*, 1972) criteria for schizophrenia and had been in hospital continuously for at least 1 year. The 92 patients taking part in the present study had continued as inpatients for a further 4 years and had remained in one of six wards caring for patients of medium dependency although not physically ill or frail. A standard therapeutic regime was in practice in those wards during the relevant 4 years and no major changes in the social circumstances or policy were made during that time. This investigation concerns the comparison of the mental states of these patients on two occasions 4 years apart using the rating scale for chronic psychotic patients devised by Krawiecka *et al* (1977) modified to separate flattening and incongruity of affect (Johnstone *et al*, 1978) so that the items rated each on a five-point scale were anxiety, depression, retardation, incongruity of affect, incoherence of speech, delusions, hallucinations, poverty of speech and flattening of affect. These ratings were conducted by E.C.J. and D.C.G.O.

A re-check of inter-rater and test-retest reliability was

TABLE I

	D.G.C.O. vs E.C.J. % agreement	*Fisher's exact P value*	*% of cases in whom feature is present at a score of more than 1*
Depression	100	<0.02	18%
Anxiety	82	NS	13.6%
Delusions	100	<0.002	54.5%
Hallucinations	100	<0.02	18%
Incoherence	91	<0.02	41%
Poverty of speech	100	<0.01	36%
Flattening	73	<0.002	54.5%
Incongruity	82	NS $P<0.06$	27%
Retardation	73	NS	9%

conducted for this investigation using videotapes of interviews with 11 patients with chronic schizophrenia (Table I).

This table shows the percentage agreements between the ratings. Because of the small numbers involved the significance of these agreements was assessed by applying Fisher's exact test to 2×2 contingency tables obtained by collapsing the five-point scale into the presence (score 2–4) or absence (score 0–1) of a pathological feature. This cut-off was chosen because a rating of 1 on the Krawiecka *et al* (1977) scale indicates a score which is not clearly pathological. In most cases the agreements between the ratings are satisfactory (Table I). The exceptions are anxiety incongruity and retardation and the lower level of significance was partly due to the scarcity of these features in the population on which reliability was checked (Table I).

The raters were blind to all treatment and historical aspects when they conducted both assessments on the 92 participants of this study and the second ratings were conducted blind to the results of the first. Details of past and current neuroleptic and other physical treatment had been obtained at the time of the first assessments and this information was brought up to date following the second interviews.

Results

The sample consisted of 31 females and 61 males. The mean ages, durations of illness and durations of stay in hospital at the time of the first rating were 58.7 s.d. 10.5 years, 32.2 s.d. 9.1 years, and 27.0 s.d. 11.9 years for females and 54.7 s.d. 12.5 years, 29.6 s.d. 10 years, and 25.8 s.d. 11.9 for males. The mean scores on each feature of the modified Krawiecka *et al* (1977) scale on the first and second occasions of rating are illustrated in Fig. 1.

Sixty-six patients were prescribed neuroleptics on both occasions on which they were rated; 18 patients were prescribed neuroleptics on neither occasion, four were taking neuroleptics the first time but not the second and the remaining four were not taking neuroleptics on the first occasion but were taking them on the second. The numbers in the groups of patients on neuroleptics on one occasion but not the other were too small to be examined usefully. Only the findings on the 84 patients consistently taking, or not taking neuroleptics have been considered and they are shown in Table II.

Significant relationships were found between the ratings on the first and second occasions of depression, delusions, hallucinations, poverty of speech and flattening of affect, but not in the case of anxiety, incongruity of affect or incoherence of speech. A significant relationship was established for retardation only in patients consistently on drugs. Since large numbers of subjects were involved in these comparisons χ^2 tests were applied to the contingency tables relating to the first and second occasion. Anxiety, incongruity of affect and retardation had relatively low inter-rater and test-retest reliabilities (Table I) and this may contribute to the lack of agreement between first and second ratings. By contrast incoherence of speech was rated very reliably (Table I). Thus the lack of agreement between the two occasions on this relatively common feature is likely to reflect its variability. The differences between the ratings in patients taking and not taking neuroleptics were examined using the Mann-Whitney U test (Table II). In this study the drugs were not randomly allocated but were prescribed on the basis of clinical need. The higher score on delusions of patients taking neuroleptics compared with those not taking them may reflect this fact. On the other hand, the fact that scores on retardation, poverty of speech and flattening of affect are higher in patients not taking neuroleptics is an indication that the abnormality being measured here is not a drug effect. This is of relevance because of the known difficulty in separating negative features from drug-induced akinesia (Rifkin *et al*, 1975). Scores of stability were calculated on the basis of percentage emergence/resolution relative to consistent presence and these are also shown in Table II.

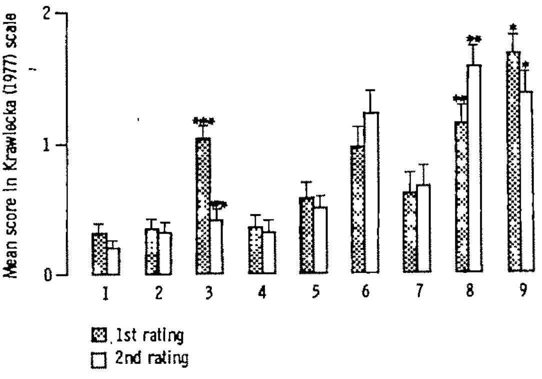

FIG. 1. Mean scores on the individual items of the Krawiecka *et al* (1977) scale in the total sample of 92 cases on the two occasions of rating. (*$P<0.05$, **$P<0.01$, ***$P<0.001$, McNemar test of changes.)
1 = Anxiety. 2 = Depression. 3 = Retardation. 4 = Incongruity of affect. 5 = Incoherence of speech. 6 = Delusions. 7 = Hallucinations. 8 = Poverty of speech. 9 = Flattening of affect.

Discussion

This study compared the stability of positive and negative features in a sample of long-stay hospital patients over a 4-year period. Of the nine features examined, anxiety, depression and retardation have been classified as non-specific features, incongruity of affect, incoherence of speech, delusions and hallucinations as positive features and poverty of speech and flattening of affect as negative features (Johnstone *et al*, 1978). In general the changes were not striking (Table II, Fig. 1). The patients showed no marked deterioration over a 4-year period but on the other hand the improvement in symptoms at ages above 55 years described by Bridge *et al* (1978) in their paper on burned out schizophrenia did not seem to be occurring.

The mean scores shown in Fig. 1 offer no information on the amount of change occurring in individual patients as changes in different directions in different patients would cancel the effect of one another. They demonstrate consistent trends across the whole population examined. Retardation showed the most change in mean score, this being significantly diminished on the second occasion (Fig. 1). The reliability of the scoring of this feature was relatively low (Table I) but while this could contribute to change it would not account for the consistent reduction in mean score. Over the 4 years of the study the patients had become better acquainted with the raters and this increased familiarity could be a plausible explanation for the lesser score on retardation and also for the less significant fall in flattening of affect. If this were so, however, it might be expected that poverty of speech would also decrease whereas it showed an increase in mean score (Fig. 1). Over the 4 years of the study the authors had discussed the difficulty of rating retardation and of separating it from poverty of speech and flattening of affect (Krawiecka *et al*, 1977). It may be that this concern led to more conservative rating of retardation on the second occasion than on the first.

Comparisons in Table II relate to the central issue of this study—the question of reversibility/stability of the features examined. The within-person ratings for retardation showed a significant relationship between first and second occasions only for patients taking neuroleptics and this feature was relatively low in the hierarchy of stability. Anxiety was the least stable of all features and although depression did show significant within-person relationships between occasions 1 and 2 it was placed at the midpoint in the hierarchy of stability.

Positive features showed a degree of variability, in that while delusions and hallucinations showed significant within-person relationships between occasions 1 and 2, and were placed fairly high in the hierarchy of stability, incongruity of affect and incoherence of speech showed no significant within-person relationships between occasions and were less stable than any other feature except anxiety.

By contrast, highly significant within-person associations between ratings 1 and 2 were found for both negative symptoms and they achieved the highest scores on stability. The study therefore provides support for the view that negative features are relatively stable and positive features relatively variable in circumstances where the effects of drug treatment and social change are likely to be minimal. It does, however, demonstrate that negative features are not entirely irreversible as they may be resolved (Table II). Indeed the frequency of resolution of flattening of affect found in this study is greater than the 6% noted by Pfohl & Winokur (1982b) in their study of 52 schizophrenic patients. It could be argued that the design of the present investigation may have led to underestimation of the difference in reversibility/stability between positive and negative features by including only patients who continued to require substantial care despite 25 years of inpatient treatment. Positive features show the greater response to drugs but there are some patients who do not show this response and continue to have such phenomena on a long-term basis (Paul, 1969). Such patients are likely to be over-represented in the present sample and indeed the frequency of positive symptoms (Table II) indicates that this is so. It is reasonable to suggest that such over-representation might reduce the amount of change in positive symptoms that would be found. This study took advantage of an unusual opportunity of minimising the effects of medication and social change. The patients are not a representative sample of schizophrenics in general and it is possible that in a more typical sample the differential reversibility/stability of positive and negative features would be greater than that found here. The difference demonstrated would be consistent with the idea that the pathological processes underlying positive and negative features may not be the same. The results do not, however, indicate that either group of symptoms is of necessity irreversible. Each of the symptoms rated were sometimes resolved in this group of patients with severe and chronic schizophrenia.

Acknowledgements

The authors wish to thank the patients and the medical and nursing staff of Shenley Hospital for their co-operation in this project. The

study was conducted under the auspices of the ethical committees of Shenley and Northwick Park Hospitals and was carried out according to their rules.

Assessing the Benefits of Psychotherapy:
The Economic Approach

G. McGRATH and K. LOWSON

Recent debate about the place of psychotherapy in the National Health Service, while emphasising the importance of economic evaluation, has concentrated almost exclusively on issues of clinical outcome. This paper argues that the debate has focussed on too narrow a definition of psychotherapy and too limited a view of the possible effects of psychotherapy, both good and bad. It reviews evidence concerning the demand and need for psychotherapy services in a number of clinical settings, and discusses the economic implications of the provision of such services. Economic studies of psychotherapy are reviewed and a conclusion drawn that it might be possible to justify the provision of psychotherapy services on economic grounds, but that considerably more research needs to be done in this area. The directions such future research might take are outlined.

Within the last two years leading articles have appeared in four influential journals expressing serious doubts about the role of psychotherapy services within the National Health Service (NHS) (Shepherd, 1984; Wilkinson, 1984; Anonymous, 1984; Gwynne Jones, 1985). These critics, and those replying in defence of psychotherapy services (Aveline, 1984; Bloch & Lambert, 1985) imply that decisions about service provision in the NHS are primarily economic decisions; nonetheless, they all fail to meet the challenge of such a view and concentrate instead on the effectiveness of psychotherapy in terms of clinical outcome alone.

The purpose of this paper is to emphasise our belief that there is a further priority than the question 'is psychotherapy effective?'; namely, the economic appraisal of psychotherapy services. We are thus not concerned solely with whether psychotherapy works, but with whether it is worth spending scarce NHS resources on its provision. We wish to establish a different framework for considering psychotherapy than clinical outcome alone, and to this end we shall consider how economic issues could be approached in psychotherapy research, and suggest a protocol for future research in this area.

In the discussion below we shall adopt a fairly wide definition of psychotherapy, based on that of the Royal Australian and New Zealand College of Psychiatrists:

> Psychotherapy is the treatment of a patient by psychological processes in the setting of a patient–therapist relationship in which the involvement of the therapist is a clearly recognised factor. No specific theoretical orientation is implied, nor are specialist behavioural treatments specifically excluded.

Economic factors in assessment

Glass & Goldberg (1977) point out that just being 'cheaper' is not a sufficient reason for preferring a course of action; 'economising' is simply cost-cutting and ignores benefits. The criterion of economic efficiency ensures that a community's resources are allocated such that the maximum benefit is derived. Alternatives are compared by reference to both costs and benefits. Such a criterion implies that a given treatment or pattern of care will not be preferred over another solely on the basis of either being less costly or more beneficial. Decisions depend on both relative costs and relative benefits.

Drummond (1980) defines four questions to which economic appraisal can address itself:

1. What is the cost of a treatment?
2. What is the benefit gained from a treatment?
3. What is the most efficient way to treat a given condition?
4. Is the treatment worthwhile?

The first two questions each refer to only half of the problem of cost–benefit analysis, and hence each can yield only half the required information.

In asking the third question, it is assumed that treatment will be given (i.e. the treatment objective is not itself in question) and hence cost-effectiveness analysis (see appendix) can be used to compare alternative forms of treatment. Examples of such studies are the comparison of methods for delivering long-term domiciliary oxygen to chronic bronchitics (Lowson *et al*, 1981) and a comparison of day care against traditional inpatient treatment for inguinal hernias and haemorrhoids (Russell *et al*, 1977).

The answer to the fourth question is often taken for granted, but logically stands before question three. The question itself can refer to different issues. For example, one could ask how much *more* (or *less*) of an already existing treatment or screening programme can be justified. Neuhauser & Lewicki (1975) assessed the costs and benefits of a series of tests for colonic cancer by measuring the additional cost for each additional true positive result. In this case the application of average rather than marginal costs would have severely underestimated the true costs.

Alternatively, *total* costs and benefits can be measured as in the study by Hagard *et al* (1976) of the introduction of a programme to screen pregnant women for spina bifida cystica in foetuses. Even when some benefits prove difficult or impossible to measure

> if it can be shown that all costs are included and that there are other positive if intangible benefits, a benefit/cost ratio of 1 . . . is a sufficient justification for arguing for the implementation of the policy (Mooney *et al*, 1980).

So how can these economic principles be applied to an evaluation of psychotherapy services in the NHS? Questions that might be considered include: How much psychotherapy can be delivered? (i.e. how large should the service be?) and how best can it be delivered? These are questions that cannot be answered simply in terms of clinical effectiveness, but only in wider economic terms. The important question for a health service with limited resources, however, is what level of resources should be channelled into psychotherapy; should we reallocate resources already utilised in the treatment of existing psychiatric morbidity into psychotherapy or allocate additional resources? In other words, is psychotherapy merely an effective, and perhaps cost-effective way of delivering psychiatric treatment to those with co-existing physical illness, or more importantly, is it a cost-beneficial way of delivering treatment?

Economic aspects of psychotherapy

When attempting to answer such questions using an economic approach there are three steps that have to be considered. Firstly it is necessary to identify the *demand* (see appendix) for services. Technically, this is a demand, usually expressed as symptoms, for subjective better health. Such symptoms are often related to psychological distress. Demand is thus related to psychiatric morbidity as it presents to health professionals, without implying that a patient is demanding any specific form of treatment. The second step is to decide whether those making the demand on services have a *need* (see appendix) for medical intervention. This is a professional decision, as is the third step—the decision as to how this need is best met. For example, is a depressive episode best treated by psychotherapy, in some other way, or by a combination of psychotherapy with other treatments?

There is clear evidence of a large demand on the health services for treatment of symptoms related to psychological distress. Such symptoms are most commonly found in general practice, or general medical and surgical settings, and are closely related to other forms of morbidity (Maguire *et al*, 1974; Goldberg, 1979; Hoeper *et al*, 1979; Goldberg & Huxley, 1980; Goldberg, 1984, 1986; Bridges & Goldberg, 1984; Orleans *et al*, 1985). There is, therefore, a high level of psychiatry morbidity in the population served by the NHS and in the main it is very difficult to separate the two subpopulations suffering from emotional disorders and physical ailments. Depression, somatic representations of psychological distress and anxiety are the three most common problems; over 80% of those with recognisable disorders have affective illnesses, or alcohol or personality problems for which psychotherapy is a recognised treatment.

The evidence is that identified psychiatric illnesses are poorly managed in medical settings, whether hospital or general practice (Marks *et al*, 1979; Goldberg & Huxley, 1980; Bridges & Goldberg, 1984; Goldberg, 1984, 1986). Patients with associated physical and psychiatric disorders have a poorer prognosis if the psychiatric disorders are left untreated (Querido, 1959; Follette & Cummings, 1967; Goldberg *et al*, 1970; Cay *et al*, 1972; Kogan *et al*, 1975; Moffic & Paykel, 1975; Whitlock & Siskind, 1979; Hawton, 1981).

Johnstone & Goldberg (1976), however, found that psychotherapy shortened the duration of such disorders. Shepherd *et al* (1966) found that psychotherapy was the treatment of choice in most cases of minor illness in general practice patients.

The benefits of psychotherapy

Yates & Newman (1980a,b) have reviewed the findings of a number of American cost-effectiveness and cost–benefit studies of psychotherapy. An important part of their review is the discussion of the 'overutilisation' of medical services. The implication is that patients presenting with physical symptoms associated with psychiatric conditions are managed in ways that focus on physical rather than psychiatric symptoms. There is no reason to suspect that this is less true in Britain than the USA, and many Health Service resources such as special investigations, medication, and inpatient or outpatient care are utilised by these patients in an attempt to alleviate their physical symptoms.

Several studies (Follette & Cummings, 1967; Goldberg *et al*, 1970; Kogan *et al*, 1975; Levitan & Kornfeld, 1981; Mumford *et al*, 1984; Borus *et al*, 1985) emphasise the 'offset effect' of decreased utilisation of services when psychiatric treatment is provided. Not only is the duration of psychiatric morbidity reduced, but physical symptoms also improve, and the utilisation of other medical services (for example radiological and pathological investigations, outpatient attendances and inpatient stay) is decreased.

Mumford *et al* (1984) and Schlesinger *et al* (1981) have reviewed the evidence for the role of psychotherapy in such patients, concluding that as well as it being an effective treatment, there are measureable changes in the use of services. The former study suggests that psychotherapeutic intervention reduces the utilisation of medical services by up to 20%; the latter confirms this finding amongst such diverse populations as alcoholics and asthmatics.

It is important to point out that an 'offset effect' should not automatically be equated with a saving in resources. Firstly, such potential cost savings are calculated at average cost; the associated marginal costs (see appendix) are often considerably lower. Secondly, the savings are not always realisable, as a large proportion of costs are fixed in the short run, for example staff salaries and capital. Any released resources could be used to treat other patient groups, or additional numbers of similar patients. Thus for example, as the length of stay is reduced, extra patients may be treated; the cost per patient is reduced, but the total cost of providing treatment for all patients (including those extra) may remain the same or even increase. In this situation, additional benefits (measured as 'cured patients' or some other index of improved health) must be set against the maintained or increased costs.

In certain situations there can be a true saving, such as treatments that reduce the consumption of drugs. A number of studies (Koch, 1979; Robson *et al*, 1984; Catalan *et al*, 1984a,b) have examined the effect of different forms of psychotherapy on the prescribing of psychotropic medication in general practice. A clinical psychologist attached to a general practice reduced the prescription of psychotropic medication by 50% (Koch, 1979) or the equivalent of 28% of the salary of a senior clinical psychologist (Robson *et al*, 1984). Catalan *et al* (1984a,b) demonstrated that counselling offered by General Practitioners (GPs) significantly reduced the prescription of psychotropic medication without an increase in the time spent with patients. Counselling may also reduce the number of GP consultations (Koch, 1979; Ashurst, 1982). The Ashurst study implies that it may be possible to pick subgroups of patients where cost offsets are more likely to accrue.

Psychotherapy may also avert hospital admission. For example, in the study of Langsley *et al* (1971) patients receiving Family Crisis Therapy were less likely to be admitted to hospital in the 18-month follow-up period and their admissions were shorter. Crisis intervention was found to be cheaper, costing on average one-sixth as much as hospitalisation at 6 months. Rosser *et al* (1983) in a study of patients crippled by chronic obstructive airways disease found that patients who were given psychotherapy had fewer hospital admissions than a control group (31% against 73%).

Similar findings are also found in the treatment of the more seriously psychiatrically ill. Psychotherapy may reduce hospitalisation in schizophrenics (Sjostrom, 1985), and 'social intervention' (including family therapy) reduces relapses (Hogarty & Goldberg, 1973; Hogarty *et al*, 1979; Leff *et al*, 1982). Lesser (1983) showed that marital therapy in a selected group of manic-depressive patients offered benefits over lithium alone.

Cost-effectiveness and cost-benefit in psychotherapy

Yates & Newman (1980b) cite only one study where "crude benefit:cost ratios have been calculated", that of Cummings (1977). However, this study in fact measured the ratio of medical costs (using the number of visits as a crude proxy for such costs) before and after receipt of psychotherapy and did not specifically include measurement of benefits.

Psychotherapy could be provided in a number of ways; it is essential that the most cost-effective is selected. Psychotherapeutic treatment in the population served by the NHS can be delivered by clinical psychologists (Koch, 1979; Robson *et al*, 1984), social workers (Shepherd *et al*, 1979), counsellors (Anderson & Hasler, 1979) and nurses (Bird *et al*, 1979; Rosser *et al*, 1983) as well as general practitioners (Catalan *et al*, 1984a,b) and psychiatrists

(Wilson & Wilson, 1985). Karon & Van den Bos (1976) report on the varying cost-effectiveness of different professional therapists, the cost of the therapist varying with discipline, salary and degree of training.

Yates & Newman (1980b) in their review point out that many methodological problems exist in the comparison of delivery by different types of therapist. Therapists within and without the health service require and receive different types of training, yet the costs of training and set-up can be high and often are not included in assessment (Rubenstein *et al*, 1978). Further, thorough evaluation of newer forms of delivery of psychotherapy, which at first sight seem less costly, (for example therapy undertaken by the client alone using manuals or cassette tapes) is limited and most studies contain little or no cost information. Studies exist which examine the method of delivery; for example the amount of client contact (Yates & Newman, 1980b), intensive inpatient vs less intensive outpatient treatment (Binner *et al*, 1973), and inpatient vs daycase treatment (Washburn *et al*, 1976). These studies appear to favour psychotherapy, both clinically and economically, yet many are inconclusive and, as Yates & Newman point out, also methodologically weak. The American Psychiatric Association's Commission on the psychotherapies (APA, 1982) found that despite a great deal of interest in cost-effectiveness and cost-benefit in recent years, most studies ignore cost-analysis, and frequently even "those studies using 'cost-effectiveness' or 'cost-benefit' in their titles present no monetised data in their method or results sections", and estimate that as much as 95% of psychotherapy research neglects the cost of treatment.

Conclusions and implications for future research

We have reviewed a wide range of evidence which suggests (a) that psychotherapy has an effect: (b) that this effect can in some circumstances be beneficial and (c) that it may, in economic terms, be possible to justify the provision of a psychotherapy service within the NHS. We have made the point that outcome measures alone are of limited value in assessing a treatment, and the well recognised difficulties in measuring outcome (Bloch, 1983) do not need reiterating here. We have also argued that an economic approach is of considerably more use when asking questions about service provision.

Most of the studies cited are of short-term therapies of a non-psychodynamic kind. This reflects the absence in the literature of economic studies of intensive psychotherapy. It is, however, clear that 'psychotherapy' as practised in the NHS has a much wider scope and application than psychoanalysis, or even than specialist psychotherapy units offering a range of treatments. Any attempt to assess psychotherapy services in the NHS must take this into account. The question 'should psychotherapy be provided by the NHS?' has entirely different connotations if the word psychotherapy is replaced by 'psychoanalysis' or 'counselling in general practice'. Thus, the question 'is psychotherapy effective?' is both fundamental, as Shepherd (1985) asserts, and also as pointless (Bloch & Lambert, 1985) as the question 'is surgery effective?" would be if taken out of context. Before asking whether it is effective, it is first necessary to define clearly what are the techniques and aims to be assessed. What is therefore implied about the assessment of psychotherapy?

1. It remains essential to evaluate the clinical effectiveness of psychotherapy. This should be done in the context of the kind of service being delivered, with the techniques and aims clearly defined. Although specialist long-term psychotherapy may be the most expensive form of psychotherapy for an individual patient, it is probable that the patients placing the greatest financial burden on the NHS as a consequence of psychiatric illness are in general medical settings (due to their large numbers) or in mainstream psychiatry (for example the large cost of treating schizophrenia; Andrews *et al*, 1985). The most urgent economic studies of psychotherapy might therefore be in these settings. The cost-offset and cost-savings studies described above provide reasonable models for similar projects in the NHS. It is necessary to define the patient group involved, the aims of treatment, and the kinds of treatment being offered. A further point is that therapist training may be a substantial cost in the delivery of psychotherapy. Ideally, these costs should be included, but an alternative would be a comparison between trained and untrained therapists working with the same patient group.

2. Secondly, there is clear need for economic markers to be included in evaluation at whatever level it is performed, whether this be studying the clinical work of one therapist or the provision of a regional specialist unit. It is by no means an easy task, but it is nonetheless important, firstly, to define all *relevant* costs (e.g. marginal not average) and secondly, to include them in any evaluation. Even if both of these are achieved there may be great difficulties in accurately measuring or putting a value on many costs, especially the 'soft' social costs such as loss of leisure time (Goldberg & Jones, 1980). Measures of cost, when taken in isolation, are also of limited use in answering questions about service evaluation,

as benefits also have to be included in the equation. Benefits may also be measured in 'soft' terms such as 'wellbeing', which are difficult to measure and ascribe an economic value. The approaches to such measurement have recently been reviewed by the Office of Health Economics (OHE, 1985) and one fruitful area in psychotherapy research could be the designing and evaluating of disability scales or health indices sensitive to the changes produced by psychotherapy.

A further dimension to the application of cost-benefit analysis should be its extension to societal costs and benefits. Benefits, such as reductions in absenteeism, sickness benefit and lost productivity may be defined as true cost savings, though not directly accruing to the providers of the psychotherapy service. Such benefits are not well documented in the studies that have been performed (Yates & Newman, 1980b; APA, 1982).

3. Thirdly, such evaluation must be accompanied by comparable evaluation of alternative forms of treatment so that they can genuinely be compared in terms of overall costs and benefits. It must be remembered that offering no treatment at all is a real alternative; all treatments should be compared with the benchmark of doing nothing. This entails special difficulties in psychotherapy research where 'placebo' or research interventions may well contain a therapeutic component (Bloch, 1983), and studies should be designed to take this into account.

4. Finally, the search must continue, not only for the most cost-beneficial treatment or combination of treatments, but also for the most cost-effective way of delivering such treatments. Even if the benefits of psychotherapy were shown to outweigh the costs, this would not necessarily justify providing a service—other treatments may produce a more favourable ratio between benefits and costs. Should a treatment be shown to be both clinically effective and have a favourable cost-benefit ratio, this does not mean it should be provided in that form. It may be possible to alter delivery of the treatment to make it more cost-effective.

This approach seems complex, but need not dissuade researchers who are prepared to grasp the issues involved and plan studies carefully. Little useful work has been done in this important area and there is much scope for further study. Small-scale studies of local service provision, at the level of single units, or even groups of therapists, can be done without the need for large input of resources, but it is important to emphasise that major studies of service provision within district or regional health authorities, or even nationally, are expensive and will require funding. We consider that economic issues are of such importance that resources for research should be allocated preferentially to studies that include an economic evaluation alongside clinical research.

Appendix

Brief definitions of some economic terms used. (In part modified from: Culyer, 1976; Drummond, 1980; APA, 1982; Office of Health Economics, 1985).

Cost-benefit analysis (CBA) aims to set all the costs involved in a procedure against all its direct and indirect economic benefits: CBA thus sets out to answer the question "Is the benefit of this treatment greater or smaller than its cost when both are measured in economic terms?"

Cost-effectiveness analysis (CEA) aims at determining the most efficient use of resources, when either the desired outcome or the available resources are fixed: CEA attempts to answer the question "Which of these alternative treatments provides better value for money given that they both achieve the same outcome?"

Cost-utility analysis attempts to measure the degree of well-being achieved by a treatment in relation to its cost. 'Utility' as a concept represents an attempt to measure and evaluate a change in quality of life. In the case of medical treatment, utility is an increase in the quality of life (Office of Health Economics, 1985).

Demand is an indication of desire to obtain a commodity. Utility represents the satisfaction gained, so the greater the utility the greater the demand. In the NHS the commodity in demand is 'better health'. Health is viewed by health economists as a 'fundamental commodity' for which demand is generated for its own sake. The demand for health care is considered to be secondary to the demand for better health.

Need is based on the assumption that the individual consumer of health care lacks relevant information on which to make judgements about the effects of treatment options open to him. The doctor decides on the quantity and type of health care required by the patient. Thus the patient's needs involve expert assessment and decision. Needs are therefore not absolute, but relate to the end being sought, involve the values of a third party (which must be made explicit in any assessment study) and can be ranked and costed.

Marginal cost is the cost of producing an extra unit of output. Fixed costs are those incurred irrespective of the quantity of output (e.g. land, buildings), variable costs vary with the level of output (e.g. special investigations performed) and average costs are fixed plus variable costs divided by the total units of output (e.g. number of patients treated). The marginal cost relates to the average cost in that if one additional unit of output costs less than the average then overall the average costs are reduced, and if it costs more then the average costs are increased. For example if patients are added into spare capacity then the marginal costs are low, and may be much less than the average if overheads have already been included. On the other hand if new buildings or equipment are required then the marginal cost may be very much greater than the existing average cost.

Marginal analysis implies that choices in health care are not usually couched in terms of whether or not one should devote any resources at all to the care of (say) neurotic patients in general practice, but whether we should give more or less resources, and to what form of treatment. In this case it is the incremental (or marginal) costs and benefits of expansion or contraction of a treatment programme that are relevant, not the costs and benefits of the whole existing programme. If the evaluation concerns setting up an entire service then marginal costs coincide with total costs.

A Test of the Social Support Hypothesis

G. PARKER and B. BARNETT

As a test of the social support hypothesis, highly anxious primiparous mothers were assigned in the post-natal stage to either a professional intervention, a lay intervention or to a control group. It was hypothesised that those receiving an active intervention (be it lay or professional assistance) would become less anxious as a consequence of a central therapeutic ingredient – social support. Improvement was assessed by measuring state anxiety levels at baseline and at 12 months, while the degree to which therapists were incorporated into the social network was assessed by the Interview Schedule for Social Interaction (ISSI), given at baseline and at 12 months. While we established that anxiety levels were significantly lowered in those receiving the professional intervention and moderately (but not significantly) lowered in those receiving the lay intervention, ISSI scores for the separate groups appeared stable over the study. Reasons are considered why ISSI scores remained unchanged while intervention groups showed a reduction in anxiety levels.

Clearly, there is now a need for rigorous studies of the effect on non-psychotic disorders of providing prosthetic social relationships, either with professionals or others Henderson *et al* (1981).

There has been increasing research interest in the proposition that deficiencies in social support place the individual at risk for psychiatric disorder and particularly depression (Brown & Harris, 1978; Henderson *et al*, 1981; Costello, 1982; Harris & Brown, 1985). In terms of mechanisms, it seems that social support acts as a buffer against adversity but absence of social support does not by itself act as a pathogen. Theoretical views differ about the relative importance of actual and perceived deficiencies in social support, and the degree to which these two components are related, as well as the degree to which need for support determines any perceived lack of support.

If perceived lack of support is a risk factor to neurotic disorders (particularly anxiety and depression) it might be expected that both the inception and maintenance of such disorders might be decreased during a time of adversity by ensuring the availability of adequate social support. We examine that proposition within a controlled, intervention study described in an earlier publication (Barnett & Parker, 1985) so that only key details will be noted here and in the next section.

A consecutive series of 630 primiparous women, married or with a live-in partner, were approached on the third or fourth day post-partum at two Sydney obstetric hospitals and asked to complete trait and state anxiety scales (Spielberger *et al*, 1970), with several exclusion criteria (e.g. poor English, seriously ill baby) being specified. All but three women accepted, and assignment was made to distinct subgroups on the basis of trait anxiety scores, with a score of 40 or more reflecting 'high anxiety', 32 or 33 'moderate anxiety', and 25 or less 'low anxiety'. As those in the high anxiety group were to be further subclassified, a larger sample of 'high anxiety' subjects ($n = 89$) was obtained than for the 'moderate anxiety' ($n = 29$) and 'low anxiety' ($n = 29$) groups, (with 11 mothers having refused, and three not completing the initial interview). Interventions were offered to two-thirds of the highly anxious subjects while the remainder acted as controls.

Thirty of the 'high anxiety' mothers were allocated to a 'lay intervention' group, which comprised the provision of experienced mothers who had volunteered to assist, and who met our requirements for a support figure who, in essence, would offer commonsense advice, general support and practical assistance. Thirty-one of the 'high anxiety' mothers were allocated to a 'professional intervention' group which comprised assistance from social workers experienced in working with mothers and children, and who would provide social support but, additionally, would consider specific anti-anxiety measures, the promotion of self-esteem and confidence, and attend to any anomalies in mother–infant, father–infant and marital interactions. Thus all those receiving active intervention were to be assigned a support-figure, which was the key treatment variable for the 'lay intervention' group and a component of the treatment package for the 'professional intervention' group. Twenty-eight mothers were allocated to the 'high anxiety' control group, receiving no intervention over the year.

Both the lay and professional support workers were provided with a suggested schedule of contact, organised so that contact (visits and by telephone) was more frequent in the early weeks but maintained over the whole year. A contact diary was maintained for each subject by the support workers. Confirmation of the social support hypothesis was tested by examining for: (a) improvement in social support scores for those receiving an active intervention, and (b) a reduction in anxiety scores in those receiving an active intervention.

Method

Members of the sample were visited in their homes by the same rater (B.B.) within 3 weeks of hospital discharge. In arranging the visits, the mothers were informed that the researchers were interested in the difficulties mothers faced with new babies and that the initial visit by the rater was to explore such issues. Following a semi-structured interview a number of personality questionnaires were administered, together with the measure of social support—the Interview Schedule for Social Interaction (ISSI). The ISSI is a measure of the perceived availability and adequacy of support from intimates and the wider social network (Henderson *et al*, 1981), and generated four scale scores for each of our subjects: 'availability of attachment' (AVAT), 'adequacy of attachment' (ADAT), 'availability of social integration' (AVSI) and 'adequacy of social integration' (ADSI). The interviewer remained unaware of each subject's group allocation until the interview and baseline ratings were completed when an envelope listing the assignment was opened. Those in the 'high anxiety' group had previously been randomly allocated to the three subgroups: lay or professional intervention or control.

Subjects were asked to complete and return questionnaires at 3, 6 and 9 months, and to attend a 1-year follow-up interview, with trait and state anxiety scores being measured on each occasion. At the second interview at 12 months the ISSI was readministered to generate a second set of social support scores.

Results

Of the 147 mothers entered in the study, 139 attended the 12-month follow-up, so ISSI details are limited to the 139 subjects completing the interview schedule on both occasions (Table I). The test–retest coefficients vary somewhat across the subgroups, with the coefficients for the total sample being 0.55 (AVAT), 0.57 (ADAT), 0.72 (AVSI) and 0.63 (ADSI), perhaps suggesting somewhat greater stability in the social integration subscale scores. We next examined whether the 'high anxiety' subjects (comprising those in groups 1, 2, and 3 and therefore irrespective of treatment status) differed from the remaining subjects allocated to the 'moderate anxiety' and 'low anxiety' group, both at baseline and at follow-up. At baseline, the 'high anxiety' subjects reported significantly less adequacy of attachment (ADAT) and significantly less availability of social integration (AVSI). At follow-up, the 'high anxiety' subjects differed significantly from the remaining subjects on all four ISSI measures, in the direction of reduced availability and less adequacy in their attachments. Thus, we established that anxious subjects returned ISSI scores suggesting certain deficiencies in social support, before and after our intervention.

The next two broad sets of analyses sought to determine whether scores on the ISSI differed for the high anxiety subjects receiving intervention as against the high anxiety controls who received no intervention. At baseline, there were no significant differences, establishing that random allocation to treatment or control group was not associated with differences in attachment scores. At follow-up, the professional intervention and control groups differed on one scale, with the professional intervention group reporting greater adequacy of attachment (ADAT). As both these groups, however, showed a rather similar reduction in scores on this measure (5% and 8% respectively), the follow-up difference would appear to be more a reflection of a pre-existing trend, which was just short of significance at baseline, reaching significance at follow-up. When the lay intervention and control groups were compared at follow-up, no significant differences were demonstrated on the ISSI scales.

In addition, a series of planned contrast analyses, using the PSY programme (Hewson & Bird, 1977), examined for changes in ISSI scores over the 12 months. Such analyses were important to control for group differences at baseline and to avoid the risks of multiple inference associated with the large number of tests used in the initial analysis. In undertaking the analyses of variance with repeated measures, the technique accepted distinction between two types of factors, namely, independent groups (i.e. treatment and control) and repeated measurement (i.e. baseline and follow-up scores). The Bonferroni procedure (see Hall & Bird, 1985) was used to control the Type 1 error rate for each family of contrasts at 0.05 and we calculated that a critical F ratio of 8.53 would be required to establish significant differences between groups and for interactions of groups with repeat measurements. Firstly, we examined for group differences on ISSI scale scores averaged over time. When all high anxiety subjects were contrasted with remaining subjects, there were significant differences for ADAT ($F=13.46$) and AVSI ($F=11.84$), but not for ADSI ($F=4.46$) or AVAT ($F=3.01$). No differences were found on any scale when lay intervention and high anxiety controls, or when professional intervention and high anxiety controls were contrasted on scores averaged over time. Secondly, interaction contrasts examined whether there were significant changes between groups over time, examining in part the ADAT difference noted in the previous paragraph. When all high anxiety and remaining subjects were contrasted there were no significant differences in change for AVAT ($F=1.42$), ADAT ($F=2.17$), AVSI ($F=0.39$) or ADSI ($F=2.51$). When lay intervention and high anxiety control scores were contrasted, no significant differences in improvement were found over time for AVAT

TABLE I

ISSI Scale	Assessment	*High anxiety*			*Moderate anxiety*	*Low anxiety*	*Comparison of groups*		
		Lay intervention 1	*Professional intervention 2*	*Control 3*	*4*	*5*	*All high anxiety groups compared with remaining groups*	*Lay intervention compared with anxiety controls*	*Professional intervention compared with anxiety controls*
AVAT	Baseline	7.3	7.2	7.4	7.4	7.6	$t=0.96$	$t=0.28$	$t=0.78$

($F=1.81$), ADAT ($F=2.17$), AVSI ($F=0.47$) or ADSI ($F=0.26$). Similarly, when professional intervention and high anxiety control scores were contrasted over time, no significant differences were found for AVAT ($F=1.60$), ADAT ($F=0.23$), AVSI ($F=0.004$) and ADSI ($F=1.76$).

One item (Q.48), which contributes to the AVSI scale, appeared particularly pertinent to our inquiry in that it questions whether, apart from those at home, there are people available "(in this town) to whom you can turn in times of difficulty? Someone you can see fairly easily whom you could trust and whom you could expect real help from in times of trouble". Only three high anxiety subjects (two professional intervention and one control) were unable to nominate any such individual before the study, and two (both lay intervention subjects) at 12 months. Over the interval 29% of the lay intervention, 34% of the professional intervention and 30% of the controls reported an increased number of such people being available, while a decrease was reported by 50% of the lay intervention, 41% of the professional intervention and 41% of the controls. This analysis suggests that the provision of a social support figure to two of the groups was not associated with a differential increase in such nominated support-figures by the subjects.

In a previous report (Barnett & Parker, 1985), we examined whether intervention was successful in reducing anxiety. When mean scores at baseline and at 12 month follow-up were compared, both intervention groups had shown a significant reduction in state anxiety levels while the change in the control group was non-significant. In a more comprehensive analysis, assessing state anxiety levels every 3 months over the 12-month study, and using planned contrast analyses again, we established that only professional intervention had a significant effect with state anxiety levels being reduced by 19%, while lay intervention was associated with a non-significant reduction of 12%, as against the 3% reduction in state anxiety levels in the controls.

Thus, while the variable of importance—high anxiety—was decreased in those receiving intervention in comparison to the controls, such an improvement was not associated with any change in the four measures of both close and diffuse social relationships.

Discussion

Our study was designed principally to assess further the proposition that a high level of maternal anxiety is a key risk factor to women in the pre-, peri- and post-natal period. In a non-clinical group of primiparous mothers, subjects were assigned to subgroups on the basis of trait anxiety scores. In a separate publication (Barnett & Parker, 1986) we report the greater morbidity of the highly anxious subgroup. At baseline they scored as more neurotic and depressed (suggesting broad dysfunction not merely expressed as anxiety), they reported more life events in the previous year and they had more negative interpretations of their pregnancy, the hospital experience and the hospital staff. They had more delivery complications, while their babies were more likely to be dysmature and slow to suckle. In the post-partum period these mothers were more depressed, had more concerns about their baby, themselves and their marriage, and were less confident about coping and their parenting capacities. Thus we argue that this subgroup of mothers had rather diffuse psychosocial morbidity and were an appropriate sample to test the effectiveness of an intervention programme with an emphasis on social support.

Two interventions were designed for highly anxious mothers, using respectively professional and lay therapists, with the key objective of lowering anxiety levels in the mothers and with the secondary objective of improving mother–child interaction. Theoretically, the social support component was integral to both interventions, being the key component to the lay therapist group while, for the professional therapist group, the orientation was more to specific therapeutic strategies. In practice, at the initial visit by the interviewer each mother received a general explanation before the results of the random assignment was known, with the interviewer suggesting that having a baby makes everyone anxious and that ways to help mothers were being explored. Mothers were told that chance would decide whether "an experienced mother with children of her own" or a social worker "accustomed to working with mothers and children" would be the "helper" for up to 1 year for those assigned a "support person", or whether they would simply be followed over the 1 year. While a clear statement was therefore made about the potential for allocation of a support-figure, we did not assess in any detail the mothers' perception of the support-figure other than that they rated the therapists in a universally complimentary way (Barnett & Parker, 1985).

While we demonstrated that state anxiety levels were distinctly reduced in the intervention groups, as against the non-significant reduction in the controls, we find no support for the view that improvement might have been a consequence of the therapist becoming a key social supportive figure. There are three broad possible explanations for these findings. Firstly, that the highly anxious subjects had optimal social networks, whether actual or perceived, disallowing improvement. Secondly, that the therapists did effect change via a social support mechanism but that the ISSI did not measure that contribution. Thirdly, that the therapists were effective for reasons that were independent of any social support contribution, and a psychotherapeutic effect must be considered when the greater success of the professionals was demonstrated.

If the therapists were incorporated into the social network of the subjects, we would expect their presence to be recorded both in the AVAT scale (assessing the presence of others who know the individual very well, who allow demands for emotional support, and with whom private feelings may be shared) and in the AVSI scale which assesses the extent of, and interaction with less intimate contacts in the social network. At baseline, the three high anxiety groups scored 7.2 or more on the AVAT scale which suggests, since the maximum score of the AVAT scale is 8.0, that the group scored as having almost optimal 'availability of attachment' before the trial. This could be an accurate assessment of the sample or a reflection of the scale tending to generate skewed scores. As the community sample surveyed by Henderson *et al* (1981) returned a mean score of 6.9 on the AVAT scale, we suspect that high scores are relatively easy to generate, perhaps because subjects find it too threatening to acknowledge certain deficiencies in their intimate relationships and/or that they judge their need for an intimate as being met. Our inclusion criteria (i.e. women with husbands or live-in partners) would favour such an effect. The ISSI has a subsidiary scale (NONAT), contributed to by questions from the AVAT scale, in which the respondent indicates that *no* intimate figure is available for those particular situations and she is *not* dissatisfied with this. Only seven subjects (5%) made such a response. The highest possible NONAT score is 7 and only two of the seven subjects scored 2, the others scoring 1, out of seven. Whether as a consequence of such sample characteristics and/or some incapacity of the AVAT scale to overcome defensive responses by subjects, such a ceiling phenomenon in our sample suggested that improvement on the AVAT scale could hardly be expected. In fact, the opposite occurred, with AVAT scores for all high anxiety subjects being lower than for remaining subjects at 12 months, although such a difference was not observed at baseline. As AVAT scores for the separate subgroups of high anxiety subjects did not change over the trial, any involvement by the therapists (be they lay or professional) was not observable in AVAT scores.

No such ceiling phenomenon was evident for our sample on the AVSI scale, with the high anxiety subgroups having mean scores of 6.6–7.2, and the maximum score for the scale being 16. These mean AVSI scores for our high anxiety subgroups are lower than the mean of 9.4 established for married community subjects by Henderson *et al* (1981). Further, we established significantly lower AVSI scores for this group in comparison to the less anxious subjects in our total sample, at baseline, follow-up and averaged over time, suggesting that our highly anxious subjects had impaired availability of social integration, with the controlled design of the study establishing that this was not merely a consequence of pregnancy status in the preceding year. Several items of the AVSI scale (e.g. respondent being asked to nominate if there are people available who may be turned to in times of difficulty or trouble, or who can be talked to if the respondent is irritated by things) clearly have the potential to incorporate a social support figure. Thus, if a social support intervention is effective as a consequence of the therapists providing social support, we would expect higher follow-up AVSI scores in subjects receiving intervention, particularly when decrements were demonstrated at baseline. However, not only did AVSI scores fail to increase for high anxiety subjects receiving intervention, they showed a general trend to decrease over the trial. As this phenomenon was relatively constant across all groups, including the moderate and low anxiety subjects, it would appear to be a reflection of the narrowing of the social world of the new mother as well as the insensitivity of the scale to the social support figure. When we specifically examined whether the number of support-figures outside the home and available in times of trouble (Q.48) had increased in those receiving intervention, we found no evidence to support incorporation of the lay or professional therapist on this AVSI item. Again, mean scores for the high anxiety subjects of 8–9 on the ADAT scale (the allowed maximum being 12) and an overall mean of 12.4 on the ADSI scale (the allowed maximum being 17) suggest that the possibility that the subjects already had relatively supportive social networks is unlikely. Not only did the therapists fail to be incorporated in the availability scales, there is no suggestion that they contributed to the adequacy measures, with adequacy scores tending to decrease rather than increase over the trial for those in the high anxiety subgroups. Clearly, these findings might not hold up if intervention were offered to a socially isolated group.

The possibilities that the therapists were effective as social support figures (but that improved social support was not detected by the ISSI) or that they were effective independent of any social support role (e.g. by psychotherapeutic effects) must be explored indirectly. At baseline assessment, the high anxiety subjects reported significantly less adequacy of attachment and a trend for less adequacy of social integration compared to less anxious subjects, differences which were significant in both scales at follow-up. We interpret this as a phenomenon associated with high anxiety, in that such subjects have at least a strong negative response bias or 'plaintive set' (Henderson *et al*, 1981) in perceiving and reporting dissatisfaction with their attachment figures, or that their social network is indeed deficient. Henderson *et al* (1981) found that higher neuroticism scores were linked with lower availability and adequacy ISSI scores, and suggested that neuroticism might affect the individual's capacity to form and maintain social relationships, as well as cause the individual to view his social relationships as inadequate. It might be anticipated that if anxiety levels were reduced in such subjects, they would be less inclined to judge social support negatively and that their social relationships would be improved. Although we established (Barnett & Parker, 1985) that subjects were universally complimentary about their assigned therapist and that contact hours were quite extensive, our failure to demonstrate improved ISSI scores in those receiving an intervention suggests an insensitivity of the ISSI to the therapists' contribution, whether as an intrinsic weakness of the measure in such situations or the subjects not 'perceiving' the therapist as relevant to the questions. The general worsening in perceived adequacy of attachment over the study across most groups suggests that the ISSI was sufficiently sensitive, however, to detect the narrowed social world of the new mother.

High test–retest coefficients are generally interpreted as suggesting stability in scores. Henderson *et al* (1981) reported 12-month correlation coefficients of around 0.75 for the ISSI scales but, after correcting for measurement error, found a very high ("almost constant") correlation for the 'availability' measures, but somewhat greater fluctuations for the 'adequacy' measures. They suggested that the availability measures have "characteristics normally attributed to personality traits . . . as though each person had his own 'natural' level of availability". Our 12-month test–retest data (with a mean coefficient of 0.62) suggest less stability than found by Henderson's group, which might be anticipated for a sample facing social adaptation such as ours, and perhaps argues against any view that the ISSI measures fixed attributes which might be insensitive to imposed changes in the social network.

Such issues bear on the validity of the ISSI measure. As a test of the concurrent validity of the measure, Henderson *et al* (1981) correlated scores by 114 community subjects with scores returned by informants about the respondents. The mean correlation coefficients were 0.42 (AVAT) 1, 0.39 (ADAT), 0.59 (AVSI) and 0.26 (ADSI). These correlations, and particularly those for the adequacy scales, are not impressive and suggest relatively discordant views between the subjects and informants. Low agreement between subjects' and informants' reports is not an uncommon finding, while high agreement may not necessarily constitute validation, particularly if reports are not truly independent (Platt, 1980). Low agreement does suggest, however, that ISSI scores may be very much influenced by subjective judgments with their attendant biases. If so, it might be expected that the provision of assistance to a group of highly anxious women would have changed their perception of social support for the better. Either the provision of a therapeutic social support figure was of little moment to the subjects or the ISSI is insensitive to such changes.

Finally, it must be conceded that even if deficiencies in social support induce psychosocial morbidity, it cannot be argued that the provision of social support will necessarily relieve that morbidity, for causal and reparative pathways are not necessarily linked. Failure to demonstrate improved ISSI scores in a sample of highly anxious women whose anxiety level was reduced cannot be interpreted as the ideal challenge to those aspects of the social support hypothesis relating to aetiology and causal mechanisms. As Henderson *et al* (1981) observed, aetiological and outcome studies require different hypotheses and research strategies. Further, in arguing for intervention trials, Brugha *et al* (1982) noted that successful intervention (to deficiencies in social relationships) does not guarantee proof of a causal link. Our failure to demonstrate successful modifications of ISSI scores does not, by contrast, then disallow a causal process linking levels of social support with the inception, maintenance and resolution of neurotic disorder. These several explanations must be conceded and assessed in further longitudinal studies.

Acknowledgement

The comments of Dr A. S. Henderson, the statistical assistance of Vijaya Manicavasagar, and the secretarial attention of Liz Murray are acknowledged with gratitude. Suicide Risk Factors:

A Comparison of Suicide Attempters with Suicide Completers

K. MICHEL

Fifty cases of attempted suicide were compared with 50 cases of completed suicide on variables reported to measure suicide risk: the seriousness of the attempt, and the circumstances in which the act occurred discriminated best. Depressive symptoms were more frequent in the suicide group and in the serious attempters' group than in the non-serious attempters' group.

Because those who attempt suicide differ in certain typical characteristics from those who complete it, the assessment of risk can be based on the assumption that the closer a person gets to killing himself, the more he resembles a person who has killed himself. The variables found to be useful in measuring suicide risk include personal and clinical characteristics (Pallis & Sainsbury, 1976; Pallis *et al*, 1982) and certain aspects of the way a suicidal act is carried out (Beck *et al*, 1974; Pallis & Pierce, 1979).

Several scales for estimating suicide risk have been developed. However, it is difficult to measure their predictive value: large numbers of patients need to be followed up in order to include at least a few cases of suicide, and important characteristics are likely to change in the course of time. Furthermore, special care given to patients thought to be at risk may invalidate an original prediction. Therefore, validation of risk factors and scales has been based on comparisons between those who attempt and those who complete suicide. Such comparisons, however, face certain methodological problems. For example, information about suicide attempters can be obtained from the individual himself, whereas information about people who commit suicide can only be collected from relatives, friends or case records. Moreover, scales have not so far been validated in populations of different socio-economic structure and culture.

The aim of the present study was to test in a Swiss urban population findings based on a population in the South of England (Pallis *et al*, 1982). Characteristics of low-intent attempters, high-intent attempters (intent is measured by scales based on the *circumstances* of the suicidal act) and suicide completers were compared. We expected the findings of Pallis *et al* to be valid also for a Swiss population, although the two countries differ in terms of social structure and suicide rate (Switzerland's rate is three times higher than that of England & Wales). To overcome some of the methodological difficulties described above, we collected all the data from relatives and friends, i.e. from similar sources for all the three groups, and used a semi-structured interviewing method.

Method

Study samples

The study samples consisted of 50 cases of attempted and 50 of completed suicide. Both samples were drawn from a catchment area covering Bern and the close surroundings, within a time span of 15 months (October 1982 to January 1984).

Suicide attempters

Patients referred to the psychiatrist on duty by the casualty department of the University Hospital of Bern (comprising about 90% of all admitted suicide attempters) were routinely reported to the research psychiatrist. Those who had clearly carried out a deliberate and potentially life-threatening act were accepted for the study, and relatives or friends were contacted. In 83 cases (62%) a contact person was either untraceable or refused to co-operate, and to complete 50 interviews it was necessary to collect 133 cases.

Suicide completers

The Institute of Forensic Medicine of the University of Bern, to which all suicides from the catchment area are referred, reported names of the cases "in which a cause of death other than suicide could reasonably be excluded". For each case permission to contact the relatives by letter had to be sought from the Coroner. The letter had been approved by an ethical committee, and it had been agreed that the relatives were not to be contacted until 4 weeks after the suicide. In 31 cases (38%) relatives refused an interview or could not be traced, and 81 cases had to be collected until 50 interviews were completed.

The interviews in the attempters' group took place between 2 days and 6 weeks (mean 21 days) and in the suicide group between 4 and 12 weeks (mean 53 days) after the event.

Data collection

A set of 37 written questions was asked in a semi-structured way. Questions covered the following areas:

Medical seriousness of the method used in the suicide act: if it represented an actual danger to life it was classified as medically serious, otherwise as not serious.

Circumstances of the suicidal act: questions covered the items of the Modified Intent Scale (Pallis *et al*, 1984), and answers were rated according to the definitions and guidelines provided by the authors.

Personal characteristics: the six items of the Risk Scale (Pallis *et al*, 1982, 1984) were applied (see Table II).

Clinical characteristics: 12 questions covering symptoms of depression and signs of alcohol and drug dependence taken from the Present State Examination (PSE) (Wing *et al*, 1974) were asked and rated accordingly (the author is trained in the use of the PSE).

Items concerning circumstances of the suicidal act and mental state which could not be rated with confidence were classified as 'unclear'; this possibility was applied relatively freely, as it seemed preferable to have no information rather than unreliable information.

The reliability of the ratings

The reliability was measured by comparing ratings of the research psychiatrist with ratings made by an independent observer psychiatrist (B.R.) from 13 randomly tape-recorded interviews. In the Modified Intent Scale there was disagreement in 15% and in the 12 PSE questions in 8% of the ratings.

In nine cases of attempted suicide, the attempter was separately interviewed in addition to the contact person. The two sets of ratings differed as follows: in the Intent Scale there was disagreement in 17% and in the clinical symptoms in 23%; in 79% of the discordant ratings the attempters reported higher levels of intent and more depressive symptoms than the relatives.

Results

There were no significant differences in sex or age (below/above 45) distribution between the 214 reported cases and the two study samples. There were more women than men in the attempters' group (30 vs 20) and more men in the suicide group (16 vs 34). Most suicide attempters and most male suicide cases were under 45 years; most female suicide cases were over 45. The mean ages in the study samples for attempters were: men 36.2, women 36.9; and for suicide completers: men 41.2, women 50.1 years.

Methods used for the suicide act

The most frequent method used for suicide attempts was overdosing: 74%. In the suicide group the most frequent method was shooting (32%), followed by jumping from high places (20%); only 18% used drugs: 22 suicide attempts were, independently from other information, classified as 'medically not serious'. Examples of serious methods were deliberate poisoning from car exhaust, shooting in the chest, jumping from the fourth floor, overdose with 70 tablets of bromazepam 3 mg. Examples of not serious methods were overdose with 20 tablets of flunitrazepam 2 mg, superficial cuts on the wrists and threatening to jump from the window while being held back by the family.

Circumstances of the suicidal act

The seven items of the Modified Intent Scale give a range of scores from 0 to 14. The mean score in the attempters'

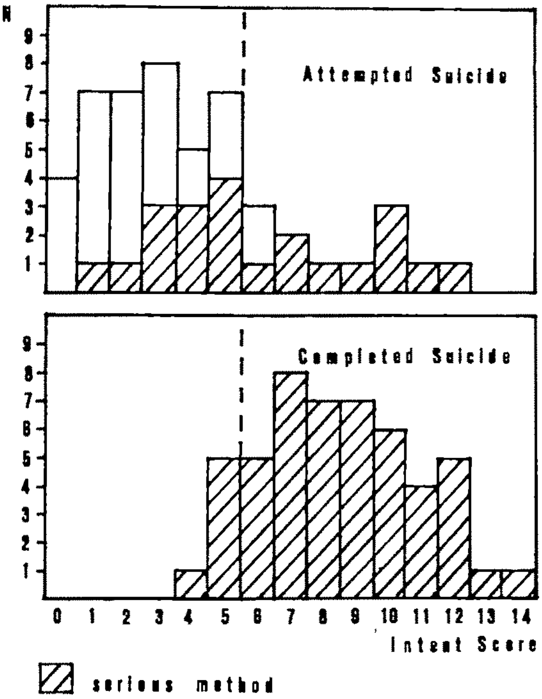

Fig 1. Modified Intent Scale: distribution of scores for the two study samples (difference between the two groups, Mann-Whitney U-test, two-tailed $P<0.001$) and their relationship to seriousness of method. Optimal cut-off line between scores 5 and 6.

group was 4.0 and in the completers' group 8.5. The distribution of scores is shown in Fig. 1.

The optimal 'cut-off line' based on the minimum percentage overlap of attempters and suicide completers lies between the scores 5 and 6 and correctly discriminates 82% of all the cases. This cut-off line was used to divide attempters into a 'low-intent' (38 cases) and a 'high-intent' (12 cases) group. Figure 1 also illustrates the association of intent with medical seriousness. In 31.5% of low-intent and 83.2% of high-intent attempters, the method was classified as serious. The mean intent score was 2.4 for the 'not serious' group, and 6.1 for the 'serious' group (the difference in the Mann-Whitney U-test was highly significant: $P<0.001$).

The distribution of scores showed statistically significant differences in six of the seven items: 1) proximity of others during act, 2) timing, 3) precautions against discovery, 4) acting to gain help during or after act, 5) final act in anticipation of death, 6) degree of planning for the act. Item 7 (presence or absence of suicide note) did not reach statistical significance.

Personal characteristics

Figure 2 illustrates the distribution of scores on the six-item Risk Scale.

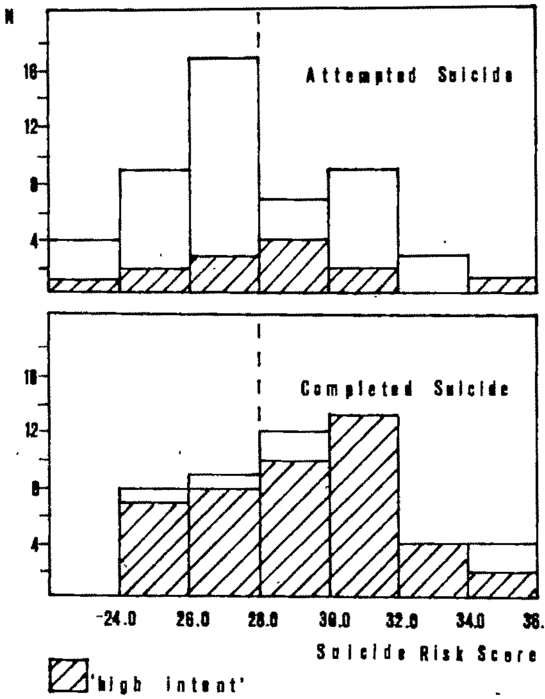

FIG. 2. Six-item Risk Scale: distribution of scores for attempted suicides and complete suicides (difference between the two groups: Mann-Whitney U-test, two-tailed $P<0.01$) and their relationship to low-intent and high-intent. Optimal cut-off point: 28.0.

TABLE I

Items of Short Risk Scale: frequency distribution of 'risk answers'

	Attempted suicide				*Completed suicide*	
	Low intent (n=38)		*High intent (n=12)*		*(n=50)*	
	N	%	N	%	N	%
Age over 45	12	31	2	16	20	40
[1]Male sex	12	31	7	58	34	68
Unemployed	6	15	1	8	15	30
Living alone	12	31	3	25	13	26
[1]Social class I+II	7	18	4	33	25	50
Suicide communications in the last year	24	63	7	58	40	80

1. Items in which the differences in the distribution of yes/no answers were significant in the χ^2-test.

The optimal cut-off line of 28.0 correctly discriminated the two samples in 64%. There was no correlation between scores on the 'Risk' Scale and the Intent Scale—the mean scores for low and high-intent attempters did not differ.

The 'risk items' appear in Table I. 'Risk answers' were found more often in the suicide group, but the differences were significant in only two of the six items.

Clinical characteristics

The ten symptoms of depression give a range of scores from 0 to 20. The man scores were 5.7 for low-intent attempters, 8.5 for high-intent attempters and 8.0 for suicide completers. Alcohol and drug abuse was associated with low depression scores, so were schizophrenia, personality disorder and, interestingly, interpersonal conflicts in adolescence (three suicide cases).

TABLE II

Symptoms of depression; percentages of score '2' answers (ratings 0–2)

	Attempted suicide		*Completed suicide*
	Low intent	*High intent*	
Symptom	%	%	%
Delayed sleep	23	36	20
[1]Early waking	3	20	55
Worrying	17	67	44
Depressed mood	26	54	30
Poor concentration	3	0	14
[1]Loss of interest	6	42	35
Social withdrawal	9	33	26
Self depreciation	14	18	26
Weight loss	9	25	31
Anergia and retardation	12	33	20

1. Significant differences in the χ^2-test.

Table II shows the percentages of score '2' answers. Differences between the three groups were significant in two of the ten symptoms.

Discussion

The aim of the study was to test the findings of Pallis *et al* in a Swiss urban population: although the study is mainly a replication of previous work, it introduces new methodological elements. To avoid the problem of having to compare data from different sources collected in different ways, information on suicide attempters as well as completers was collected by interviewing relatives or close friends of the individuals in a semi-structured way. Both study samples came from the same catchment area and were consecutively collected within the same time-span. The main problem we encountered was the refusal of a high proportion of contact persons to be interviewed. However, because we had case notes of all the cases accepted for the study, we were able to compare them with the sex- and age-distribution of the study samples, and we found no significant differences in the χ^2 test. We can therefore assume that our samples were fairly representative of the total group.

Firstly, we found a strong association between medical seriousness and scores of the Intent Scale. People who made careful preparations to kill themselves used methods presenting a high threat to life. This association has been described by Pallis & Sainsbury (1976).

Secondly, the Modified Intent Scale discriminated well between suicide attempts and completed suicides: based on the optimal cut-off point the accuracy was 82%. The results are similar to those of Beck *et al* (1974) who compared suicide attempters and completers on eight items of the Suicidal Intent Scale.

Thirdly, although the differences of the scores of the six-item Risk Scale were significant in the Mann-Whitney U-test and clearly followed the same tendency as the samples of Pallis *et al*, they were somewhat less than expected. It is interesting, however, that the cut-off point of 28.0, which accurately discriminated 64% of the cases, lies between the cut-off points of Pallis and Sainsbury's original group (28.5) and their validation group (27.5). We could not find an association between personal characteristics and intent scores as had been reported by Pallis & Sainsbury. Because the data of this scale are of an objective nature (age, sex, work status, etc.) the differences in the results cannot be due to differences in the method of data collection. They could, however, be due to differences in the sampling method (our suicide attempters had all been sent to hospital, most of them by General Practitioners and therefore represented the rather more serious cases; Pallis & Sainsbury had found medically serious attempts in 15% of their cases, while in our study this proportion was 44%), or they could reflect differences between populations in the South of England and Switzerland.

Fourthly, suicide attempters and completers differed in their amount of depressive pathology. High-intent attempters had as much pathology as suicide completers, which supports the original hypothesis that individuals at risk resemble persons who have committed suicide. It would be interesting to know which symptoms of depression are of special importance in the assessment of suicide risk. In our samples only two of the symptoms reached differences large enough to be statistically significant, while Pallis *et al* had described larger differences in more symptoms. Measuring depressive pathology 'second hand' in an objective and comparable way is difficult (the PSE-questions we used were designed to evaluate the symptoms and signs of a person being interviewed directly), and although we know that a diagnosis of depression is frequent in individuals who commit suicide (Robins, 1981; Barraclough *et al*, 1974), to our knowledge depressive symptoms in suicidal persons have not so far been measured and compared in a standardised way.

The results have clear implications on the assessment of suicide risk in Switzerland: the seriousness of method, the Intent Scale, the six-item Risk Scale and the amount of depressive pathology all can differentiate, in an urban population, between those suicide attempters who are not at risk and those who do accomplish suicide and should therefore be applied in clinical practice. The findings are similar to those in the South of England (and in Philadelphia), although Switzerland differs in many ways. The Swiss population has few social problems and little unemployment (under 1%) but has one of the highest suicide rates (27/100 000 in 1982) in the Western world. Also, the proportions of the various methods used for suicide are different in Switzerland: more than half of our suicide completers used firearms or jumped from high places: methods that are rare in England and Wales. A comparison of suicide statistics (for England and Wales: McClure, 1984) e.g. shows that our study samples have a relatively high proportion of cases from the younger age-group. Such factors might be a reason why the six-item Risk Scale was less powerful in discriminating between suicide attempts and completed suicides than expected from the findings of others. A comparison of social factors associated with suicidal behaviour might shed more light on the driving forces of suicidal behaviour and thus lead to more effective prevention.

The Impact of a Liaison Psychiatry Service on Patterns of Referral in a General Hospital

A. BROWN and A. F. COOPER

A retrospective study of psychiatric referrals from a general hospital inpatient population was carried out for three separate years, 1973, 1976 and 1979. Reorganisation of the liaison service to the responsibility of one consultant team was associated with changes in referral rate and disposal. In particular, there was a significant increase in the referral rate of patients from medical and surgical wards who were not involved in acts of deliberate self-harm.

The association between physical illness and psychiatric morbidity is now well recognised (Lloyd, 1977) but the extent to which psychiatrists are involved in the management of inpatients in general hospitals is very variable. Historically, the uncertain relationship between general medicine and psychiatry in Britain has passed through several phases. Traditional psychosomatic medicine had little impact on clinical psychiatry earlier this century (Gath & Mayou, 1983). In the 1950s, psychosomatic concepts proposed by Alexander (1952) and others attracted attention for a time but soon fell into disfavour on account of claims which were over-inclusive and theories which were difficult to substantiate (Lipowski, 1977; Gomez, 1981). However, in the 1960s the trend appeared to change following the development of consultation–liaison psychiatry, particularly in the United States (Lloyd, 1980). With a few exceptions (Crisp, 1968; McLeod & Walton, 1969) the concept of liaison psychiatry in its fullest sense i.e. the psychiatrist's integral involvement in the management of general hospital patients, has never developed as fully in the UK as in the USA, in contrast to the advances that have taken place in the management of deliberate self-harm.

In most general hospitals, psychiatrists offer a regular consultative service to their non-psychiatric colleagues but the types of service offered and the referral rates vary greatly (Brooks & Walton, 1981). Referral rates are consistently higher in the USA than in the UK (Lloyd, 1980) but in neither case are they commensurate with the levels of psychiatric morbidity found amongst general hospital in-patients (Maguire *et al*, 1974). Analysis of the type of referrals made to liaison services has been carried out at a number of centres (Fleminger & Mallett, 1962; Anstee, 1972; Fava & Pavan, 1980) but few recent studies have examined the trends in referral patterns over time. In October 1974, a liaison psychiatry service, staffed by one consultant team, was introduced to the general wards of the Victoria Infirmary, Glasgow. In the course of the next few years, a rise in the annual referral rate was noted (Fig. 1) and this paper sets out to examine the nature of the changing pattern of referrals to the liaison service.

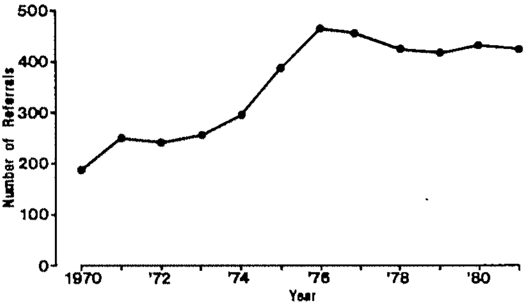

FIG. 1. Annual referral rate of Victoria Infirmary inpatients to the liaison psychiatry service.

Description

The Victoria Infirmary is a 500-bed general hospital, without a psychiatric in-patient unit which, during the time of the study, served the population of Greater Glasgow Health Board, South Eastern District, approximately 200,000 people. Prior to October, 1974 patients referred by physicians and surgeons were seen in the wards by psychiatrists from the associated psychiatric hospital, Leverndale Hospital, situated 6 miles away. Consultations usually took place on a twice-weekly rota basis during the course of outpatient sessions held at the Victoria Infirmary. Since that date, referrals from the general wards have been the responsibility of one of the Leverndale clinical teams consisting of the consultant and one trainee psychiatrist who have devoted three sessions per week to liaison psychiatry.

Initially, all patients were seen in the medical or surgical wards, but in 1976, accommodation adjacent to the medical wards became available for psychiatric staff to interview patients in privacy. Referrals are made by letter and an appointment system is operated. Patients are brought to the Department of Psychiatry by ward staff and the management of each is discussed with appropriate medical or nursing staff before the end of each liaison session.

Method

A retrospective case-record study was carried out on all patients referred for a psychiatric opinion in 1973 (the last full year prior to the introduction of the liaison service); and also those referred during 1976 and 1979. Information was obtained from both general hospital and psychiatric hospital case records and from contact sheets used by the local psychiatric service. The following data were recorded: age and sex of referred patient, source of referral, previous contact with the psychiatric services, presence of self-poisoning or injury, primary psychiatric diagnosis and disposal.

Information relating to admissions to the Victoria Infirmary and to Leverndale Hospital and the number of referrals to the psychiatric outpatient clinics in the catchment area was obtained from the Information Services Division, Greater Glasgow Health Board. The significance of differences between the samples was assessed by χ^2 analysis and in view of the large number of patients and tests of significance involved, $P<0.01$ was taken as the criterion for statistical significance (Altman *et al*, 1983).

Results

Demographic features

The mean ages of the referred patients were 35.7 years (1973), 40.6 years (1976), 40.9 years (1979). Consistently the highest number of referrals was in the age-range 20–29 years and in each year, approximately 75% of the patients were between 20 and 59 years of age. The ratio of male to female patients remained fairly constant (1/1.85 in 1973 and 1976; and 1/1.91 in 1979).

Diagnostic categories

Diagnoses were made initially according to the ICD-9 classification (WHO, 1978) and were then grouped into nine categories. The results relative to the primary diagnoses are shown in Table I.

In several categories, e.g. alcohol and drug addiction and organic brain disorders, the percentage of patients diagnosed remained approximately constant, whereas in others, e.g. personality disorder and situational disturbance, there was a significant change. This probably represents a variation in the fashion and priorities for psychiatric diagnosis rather than an alteration in the patient population. This conclusion is supported by observing the results obtained when the percentages in diagnostic categories 1 and 2 were combined and those in categories 3 and 4 were also combined (Table I). Comparable totals for each of the three years studied were obtained for each category. Thus, 41–45% of patients were diagnosed as personality disorder and situational disturbance, and 28–32% as suffering from depressive illnesses.

A separate analysis was carried out for the group of patients who had not harmed themselves (50 in 1973; 127 in 1976; 112 in 1979). Whilst there was a decline in the frequency of a primary diagnosis of personality disorder over the years similar to that in the total group, the diagnosis of depressive illness increased from 4 (8%) in 1973 to 34 (27%) in 1976 and 31 (28%) in 1979. The diagnosis of neuroses (other than depressive) also increased from 4% in 1973 to 8% in both 1976 and 1979 whilst that of alcohol and drug-related problems decreased from 26% in 1973 to

TABLE I

Primary psychiatric diagnoses (approximate % in parenthesis)

Diagnosis	*1973*	*1976*	*1979*	*P(d.f. = 2)*
1. Personality disorder	56 (22)	53 (11)	20 (5)	<0.001
2. Situational disturbance	47 (19)	147 (32)	166 (40)	<0.001
3. Neurotic depression	66 (26)	80 (17)	68 (17)	<0.01
4. Endogenous depression	14 (6)	68 (15)	48 (11)	<0.01
5. Alcohol and drug addiction	34 (13)	56 (12)	42 (10)	NS
6. Organic brain disease	16 (6)	31 (7)	26 (6)	NS
7. Other psychosis	12 (5)	16 (3)	14 (3)	NS
8. Other neurosis	5 (2)	11 (2)	18 (4)	NS
9. No diagnosis	2 (1)	6 (1)	18 (4)	<0.01
Total	252	468	420	

TABLE II
Disposal (% in parenthesis)

	1973	*1976*	*1979*
GP only	93 (37)	130 (38)	180 (43)
Outpatient follow-up	111 (44)	195 (41)	131 (31)
Inpatient care (Leverndale)	33 (13)	64 (14)	50 (12)
Other	15 (6)	79 (17)	59 (14)

21% in 1976 and 12% in 1979. The diagnosis of organic psychosyndromes in this group was high but relatively constant at around 25%.

Disposal

Table II shows the pattern of disposal of patients following consultation. The percentage followed up as outpatients fell significantly during the period 1976–1979 ($P<0.001$) and this was entirely due to a reduction in the follow-up rate of the deliberate self-harm group ($P<0.001$). The proportion of patients transferred to psychiatric inpatient care, however, remained constant. A consistent majority in the latter group were patients previously known to the psychiatric service (55–60%) and most had harmed themselves (1973:79%; 1976:64%; 1979/76%).

TABLE III
Number, source and type of referral (% in parenthesis)

Referrals	*1973*	*1976*	*1979*
Total referrals	252	468	420
Referred by physicians	227 (90)	418 (89)	365 (87)
Deliberate self-harm (DSH)	202 (80)	341 (73)	308 (73)
Non-DSH	50 (20)	127 (27)	112 (27)

Referral rates

Table III shows the total number of referrals to liaison psychiatry in each of the three years studied, the number referred by physicians and the numbers of cases of deliberate self-harm (DSH) and non-DSH patients. The vast majority of patients referred were cases of DSH and from physicians, but an increased proportion of non-DSH referrals was noted after 1973.

Table IV shows the referral rates of various categories of admission i.e. the number of patients referred divided by the total number of admissions to the Victoria Infirmary in each category. There was a significant increase in the referral rates of all admissions to the Victoria Infirmary, of admissions to the medical wards and of non-DSH patients. However, there was no significant change in the referral rates of patients indulging in self-harm despite the fact that the commitment to liaison psychiatry was increased by one session per week.

TABLE IV
Referral rate of various categories of admission to Victoria Infirmary

	1973	*1976*	*1979*	*P (d.f. = 2)*
Total referrals	252	468	420	
Total admissions	13594	14811	14991	
Referral rate	1.85%	3.16%	2.80%	<0.001
Referrals from physicians	227	418	365	
Total medical admissions	3388	3686	3922	
Referral rate	6.7%	11.3%	9.3%	<0.001
DSH referrals	202	341	308	
DSH admissions	347	536	551	
Referral rate	58.2%	63.6%	55.9%	NS
Non-DSH referrals	50	127	112	
Non-DSH admissions	13247	14275	14440	
Referral rate	0.38%	0.89%	0.78%	<0.001

The possibility that the rise in referral rate was merely a reflection of rising psychiatric morbidity in the community was investigated by comparing total liaison referrals and non-DSH liaison referrals in each year with the number of referrals made to the associated district psychiatric outpatient clinics and inpatient psychiatric wards. The results in Table V show that the increase in both total and non-DSH liaison referrals was significantly different from these other indicators of psychiatric morbidity.

TABLE V
Comparison of liaison referrals, new outpatient psychiatric referrals and psychiatric admissions

	1973	*1976*	*1979*
A. Total liaison referrals	252	468	420
B. Non-DSH liaison referrals	50	127	112
C. Total new outpatient psychiatric referrals	959	1148	692
D. Total psychiatric admissions	973	1074	1086

For comparisons A vs C, A vs D, B vs C and B vs D: $P<0.001$, d.f. = 2.

Discussion

Reorganisation of the liaison psychiatry service to a general hospital provided a natural experiment in which the impact of the work of a single liaison team on patterns of referral could be investigated. There appears to be only one recent study in which changes in the pattern of referrals to a liaison service over time have been studied. Lipowski & Wolston (1981) compared two consecutive populations of 1000 patients referred to a liaison service during an 8-year period and emphasised the stability of the populations in relation to demographic characteristics, diagnostic categories and patterns of referral and intervention.

Despite the widely differing proportions of patients indulging in deliberate self-harm (8% of Lipowski & Wolston's patients and 73–80% in the present study) the demographic characteristics of the two populations are similar; 75% of the present sample being between 20 and 59 years in each year examined, compared with 70% in the other study. The ratio of female to male patients is also slightly higher in the present series, 1.85–1.91:1 compared to 1.6–1.8:1. These results are similar to the findings of Fleminger & Mallett (1962) and Fava & Pavan (1980).

Comparison of the distribution of the psychiatric diagnoses in the two studies is limited by the use of different classifications. For example, the first two categories are not specifically represented in Lipowski & Wolston's paper. The proportion of depressive disorders found in our patients is markedly less (28–32% compared to 43–50%) as is the percentage of patients with organic brain syndromes (6% compared to 14–15%). The latter finding may be a reflection of the much higher proportion of patients presenting with deliberate self-harm in the present study since, when these are excluded, the percentage of organic disorders rises to 22–28%.

The very high percentage of referrals from physicians in this study (87–90%) is probably related to the high proportion of cases of deliberate self-harm. However, when these are excluded, the referral rate from physicians (58–66%) is still higher than from other specialties and is similar to the 60% reported by Lipowski & Wolston (1981).

The change in pattern of disposal, particularly the significant reduction in the follow-up rate of those who had harmed themselves, is probably the result of a conscious alteration in the management of these patients. There is increasing awareness that even intensive follow-up does not significantly alter repetition rates (Chowdhury *et al*, 1973; Gibbons *et al*, 1978; Hawton *et al*, 1981), and that a reduction in repetition rates is more likely to occur when psychiatric assessment and advice takes place before discharge from hospital (Greer & Bagley, 1971; Kennedy, 1972). The high default rate of these patients at subsequent outpatient appointments is well recognised (Morgan *et al*, 1976; Blake and Mitchell, 1978). In contrast, however, a relatively constant proportion of patients require psychiatric inpatient care for further assessment and treatment.

Referral rates to the liaison service are comparable to those elsewhere in the UK (Lloyd, 1980) but these rates are much lower than the reported rates of psychiatric morbidity found in medical wards (Maguire *et al*, 1974). There are several possible reasons for this. Estimates of psychiatric morbidity may be excessive, the psychiatric services may be inadequate, psychiatric disorder may not be recognised or, if recognised, may be treated by the non-psychiatric specialist or general practitioner (Mezey & Kellett, 1971). Several authors have commented on the resistance of other specialists to referring their patients to psychiatrists. The problem is often attributed to the patient but may in fact reflect reluctance on the part of the referring specialists themselves (Steinberg *et al*, 1980).

Unlike the increase in referral rates observed in another British study (Anstee, 1972), the rise in referral rate over the period of this investigation is not attributable to increased referral of cases of deliberate self-harm. It is noteworthy that the maximum rate of referral in this group was only 63.6%, despite government recommendations (Ministry of Health, 1961) that all such cases should have formal psychiatric assessment.

The most striking finding in this study is the significant increase in the referral rate of medical and surgical inpatients who are not involved in acts of deliberate self-harm. This does not appear to be associated with a rise in psychiatric morbidity generally, as measured by the rate of admissions to the local psychiatric hospital and outpatient referrals to the psychiatric service at the time. It is encouraging to note that the rise in referral rate is associated particularly with an increase in the diagnosis of potentially treatable conditions such as depressive illness and neurotic disorders.

The results suggest that the changes observed in the pattern of referrals are related to the interaction between the reorganised liaison service and the referring departments. The identification of a specific liaison team may lead to improved interprofessional relationships, an increased awareness of the importance of psychological factors in physical illness and a more well defined and realistic expectation of the service provided. Crisp (1968) reported a referral rate of 10% of inpatients from two medical wards to his liaison service and emphasised that personal contact with the physicians was a major factor determining the extent of referrals of patients for psychiatric opinion. Other authors have attributed changes in both rate (Torem *et al*, 1979) and specificity (Davis & Nelson, 1980) of referral to liaison services, to increased contact with the referring departments. The present study demonstrates that even a modest reorganisation of the liaison psychiatry services to a general hospital can be associated with a significant increase in the referral rate of patients in medical and surgical wards.

The Persistence of Prescribing Habits:
A Survey and Follow-up of Prescribing to Chronic Hospital In-patients

A. F. CLARK and N. L. HOLDEN

This study describes a survey of prescribing to psychiatric patients on long-stay wards, together with a follow-up survey carried out after a 2-year period. Our findings show that there had been no significant improvement in polypharmacy and overprescribing of psychotropic drugs over that period, 1983–1985. Guidelines for improvement are suggested.

The theoretical aspects of rational pharmacotherapy have been discussed extensively (e.g. Ayd, 1973). Recently, with increasing interest in medical audit, there have been a number of surveys of prescribing in psychiatric settings. The first British study, carried out in an Oxford hospital, was reported by Michel & Kolakowska (1981) and highlighted the problems of polypharmacy and illogical prescribing.

A further study of patients in Malvern (Morgan & Gopalaswamy, 1984) found similar results, but criticised the earlier survey by attempting to show that illogical polypharmacy could be explained when patients' diagnoses and individual needs were reviewed in conjunction with the survey. However, although this approach may partly explain the reasons for polypharmacy, it does not lessen the value of identifying extensive overprescribing (Holden, 1984). The findings of the Oxford survey have been replicated by Edwards & Kumar (1984) in a survey carried out on a similar patient population in Birmingham. This present study was carried out to see if similar results would be found in a survey of prescribing to a dissimilar population of psychiatric patients, and to investigate the stability of prescribing over a 2-year period in the light of the above research and publicity.

Method

The population studied was of patients on long-stay wards of a large psychiatric hospital, serving the catchment area of the whole of Newcastle. This hospital is a designated teaching hospital for undergraduate and postgraduate psychiatric teaching. The wards involved have high bed occupancy (in the region of 98%) and low turnover (10–15 new admissions per quarter with dementia, and 2–4 with 'chronic functional' illnesses) in common with such wards elsewhere in the country. All patients on these wards are reviewed fully, at least at 6-monthly intervals, as well as receiving more frequent medical attention when necessary.

The patients were divided into two groups, those suffering from 'chronic functional disorders' (predominantly schizophrenia and affective disorders) and those with 'organic mental disorder' (predominantly middle- and late-stage of dementia of mixed types). Division into these groups was done by reference to the patient's casenote diagnosis.

The initial survey was carried out within a single day in March 1983, and the follow-up survey within a single day in July 1985. Ward staff were not forewarned prior to either study. All medication listed in the British National Formulary within the section on 'Drugs acting on the central nervous system' was recorded as psychotropic medication. 'As-required' medication was only included if it had been administered within the immediately preceding 24 hours.

During the 2-year period between the surveys, the results of the initial survey were published briefly (Holden, 1984). In addition, further attention was drawn to the problems of prescribing by the publication of the surveys mentioned above. However, no attempt was made to approach care-workers directly over the individual patients' findings.

Results of the two surveys were compared using the chi-squared test. However, it should be made clear that this test depends on the assumption of the independence of the observations in the two surveys, and as there were some patients and therapists common to both, this is not strictly the case. However, since no other simple statistical test is more applicable to this situation, and the chi-squared test underestimates the likelihood of findings being significant in this case, its use was felt to be acceptable.

Results

In the 1983 survey, there were 139 patients in the chronic functional disorders ('chronic') group — 60 males (age range 37–85, mean = 67.9, s.d. = 9.2) and 79 females (age range 34–85, mean = 63.1, s.d. = 12.1) — and 174 patients in the organic mental disorder ('organic') group — 33 males (age range 53–89, mean = 73.2, s.d. = 9.0) and 141 females (age range 46–100, mean = 80.3, s.d. = 7.9). In the second survey, there were 156 patients in the 'chronic' group — 61

1. χ^2 showed no significant differences for all comparisons 1983–1985.
2. χ^2 showed no significant differences for all comparisons 1983–1985 except total drugs prescribed increased, $P<0.05$.

males (age range 52–88, mean = 69.6, s.d. = 7.2) and 95 females (age range 31–105, mean = 67.7, s.d. = 14.7)—and 137 patients in the 'organic' group—42 males (age range 27–90, mean = 69.5, s.d. = 12.6) and 95 females (age range 52–100, mean = 79.9, s.d. = 11.0). Almost all of the patients were white Caucasian (>99%).

In the 'chronic' group (Table I), 9% of patients were receiving no psychotropic medication in 1983 and 15% in 1985, with 46% receiving three or more psychotropic drugs in 1983 and 42% in 1985. In 1983, 84% of patients were receiving neuroleptics and 76% in 1985. Of those prescribed neuroleptics, 39% were receiving two or more and 25% both depot and oral forms in 1983, increasing to 43% and 30% respectively in 1985. In the 1983 survey, 56% of the whole group and 63% of those who were receiving neuroleptics were also receiving anticholinergic anti-parkinsonian agents, in contrast with 43% and 55% in the 1985 survey. Those prescribed multiple neuroleptic medication were significantly more likely to receive anticholinergics ($\chi^2 = 20.4$, d.f. = 2, $P<0.001$).

Hypnotic drugs were prescribed to 21% of the 'chronic' patients in 1983 and to 25% in 1985. These were combined with an antidepressant or a neuroleptic in 86% in 1983 and 79% in 1985. The percentages of patients receiving other groups of psychotropic drugs in both surveys were low. There were no significant changes between 1983 and 1985 in any statistical comparison.

Drugs for physical problems were given to 60% of 'chronic' patients, the most common being laxatives (23% of all patients), diuretics (15%), vitamins (13%) and topical preparations (13%). Drugs were administered four times per day in 39%, three times in 40%, twice in 15% and once in 4%.

In the 'organic' group (Table I), 39% were receiving no psychotropic medication and only 4% three or more psychotropics in the first survey, these figures being 40% and 13% in the second. Approximately one-third of patients were receiving neuroleptics in both surveys and most of these were given orally.

Only 6% received two or more neuroleptics in the 1983 survey, increasing to 15% in 1985. In both surveys, 9% of patients received anticholinergic antiparkinsonian agents and these drugs were given to approximately 20% of those receiving neuroleptics. Just over 30% of patients received hypnotics, and of these 40% were also given a nocturnal neuroleptic or antidepressant. Only small numbers of patients were receiving other groups of psychotropic drugs, and no patients received lithium therapy. Total psychotropic prescribing for the 'organic' group increased significantly from 1983 to 1985 ($\chi^2 = 9.39$, d.f. $= 3$, $P < 0.05$), but there was no other statistically significant change.

Drugs for physical ailments were given to 73% of 'organic' patients, the most common being laxatives (45% of all patients), diuretics (25%), topical preparations (13%), vitamins and nutrients (11%) and analgesics (10%). Drugs were administered four times per day in 11%, three times in 30%, twice in 22% and once in 28%.

Comparing the prescribing patterns of both psychotropic and physical medication for the two groups in the 1983 survey, 'organic' patients were prescribed significantly fewer drugs — 82% being on three or less drugs compared with 48% of 'chronic' patients ($\chi^2 = 40.7$, $P < 0.001$). Significantly fewer 'organic' patients (41%) were administered drugs three or more times per day compared with 'chronic' patients (73%) ($\chi^2 = 30.58$, $P < 0.001$) and drugs for physical illness were prescribed to the 'organic' group more frequently than to the chronic group ($\chi^2 = 5.5$, $P < 0.05$), especially diuretics ($\chi^2 = 4.87$, $P < 0.05$), laxatives ($\chi^2 = 16.12$, $P < 0.001$) and anticonvulsants ($\chi^2 = 3.85$, $P < 0.05$).

The 'chronic' group were given significantly more neuroleptic medication ($\chi^2 = 93.5$, $P < 0.001$) and anticholinergic antiparkinsonian ($\chi^2 = 83.46$, $P < 0.001$) than did the 'organic' group. Of patients on neuroleptics only, 20% were receiving them once daily and 60% more frequently than twice daily. The most commonly chosen neuroleptic in both groups was thioridazine. More than one-half of both groups were given anticholinergic antiparkinsonian drugs as a three-times-daily dosage. The 'organic' group received more hypnotic medication than did the 'chronic' group ($\chi^2 = 5.99$, $P < 0.05$) but fewer minor tranquillisers ($\chi^2 = 15.56$, $P < 0.001$). Similar differences were found for the 1985 survey.

Discussion

Extensive polypharmacy was found in both the surveys, mainly in the 'chronic' group, but also in the 'organic' group. In the 'chronic' group, of the three-quarters of patients who were receiving neuroleptics, over one-third were given more than one type, and over 10% were receiving three or more types of neuroleptic. Between 20 and 30% of these 'chronic' patients received both depot and oral forms. The prescribing of two or more neuroleptics to stable chronic patients is hard to justify (Morgan & Cheadle, 1974; Kimball & Glass, 1983).

Anticholinergic antiparkinsonian agents (anticholinergics) were prescribed to a large number of patients, especially those who were receiving multiple neuroleptics. In a study of the withdrawal of these drugs in patients on neuroleptics in this same hospital, McClelland *et al* 1974 found that all but 8% of patients could have anticholinergics discontinued after the acute phase. Similar findings have been found by Klett & Caffey (1972), but Rifkin *et al* (1978) found that over 50% of patients withdrawn from procyclidine developed extra-pyramidal symptoms. Perris *et al* (1979) have suggested that the prescription of combined neuroleptics and anticholinergics increases the likelihood of tardive dyskinesia, and Kane & Smith (1982), whilst concluding that there was currently insufficient clinical data to confirm this, still emphasised the importance of their judicious use.

About one-quarter of 'chronic' patients were receiving nocturnal hypnotics as were approximately 30% of 'organic' patients. In addition, 80% of these 'chronic' patients and 40% of these 'organic' patients were prescribed sedative antidepressants and neuroleptics. The use of nocturnal doses of the latter drugs might allow minimisation of the use of hypnotics.

Large percentages of both groups of patients received drugs for physical ailments. They were given to 60% of 'chronic' patients and 73% of 'organic' patients. The high percentage of patients receiving laxatives probably reflects the constipating anticholinergic side-effects of the polypharmacy. Particularly unusual was the high level of regular topical medication given to patients. The fact that more than 10% of patients were on vitamins or other nutrients makes one wonder about the nutritional value of diet provided in an NHS hospital.

This survey showed that drugs were administered an excessive number of times per day to the majority of patients, and that drugs with long half-lives were given in divided dosages, often three or four times daily. Although patients may show fewer side-effects from divided doses of drugs when initially prescribed, Ayd (1973) suggested that it is illogical to prescribe drugs with a long half-life in divided doses after this initial phase. This would apply to neuroleptics, antidepressants and anticholinergics. Administering the majority of drugs once daily would save nursing time, decrease the chance of errors in administration and improve patients' willingness to comply.

The differences found between the 'chronic' and 'organic' groups were as expected. The 'organic' patients were receiving significantly fewer psychotropic drugs including fewer neuroleptics, but significantly more drugs for physical ailments. All these findings are consistent with the 'organic' group being less psychotic and having more age-related illness and deterioration.

In the population studied, patient turnover was low. The decrease in numbers in the 'organic' group in 1985 was due to the closure of approximately 50 beds for financial and administrative reasons, and may have resulted in the 1985 patients being generally more dependent. This might explain the increase in medication levels in this group. However, there remains the fact that there was no evidence of reduction of levels of prescribing over the period of study. Long-stay hospital inpatients are likely to be on stable medication for long periods, as there is undoubtedly a tendency not to change a patient's medication unless there is a change in his mental state, and administration of drugs by nurses allows medical staff to be more confident of compliance when multiple drugs are prescribed. As the effect of rapid changes in medication is minimised, the results cannot be explained as artifacts caused by transition between acute and maintenance medication. The lack of change, in spite of the publication of some of the results of the first survey (Holden, 1984) and the findings of other drug surveys, is somewhat surprising and highlights the difficulties of medical audit and resistance to change.

Comparison with the previous British studies of Michel & Kolakowska (1981) in Oxford and of Edwards & Kumar (1984) in Birmingham is difficult, as both studies looked at all patients, including day-patients. Compared with this study of long-stay patients, they showed more patients receiving depot neuroleptics, and higher levels of prescribing of anti-depressants and lithium. However, this is expected from the nature of the present sample—chronic inpatients dominated by the diagnoses of chronic schizophrenia and dementia.

Morgan & Gopalaswamy (1984) have criticised the approach used in this and other studies which does not look at the individual patient's diagnosis and needs for medication. However, we would maintain that surveys of prescribing indicate areas that can be improved. In the light of this survey, we would like to see more drugs being given as once-daily doses, with fewer drug administrations by nurses per day, and decreased chronic prescribing of anticholinergics with neuroleptics. Chronic patients should be given only one neuroleptic, either by depot or oral administration. Reorganisation of medication so that it is given mainly at night might avoid the need to give hypnotic medication. Changes along these lines would save expenditure on drugs, decrease side-effects and errors, and allow more nursing time to be spent with patients instead of administering drugs.

We would agree with Diamond *et al* (1976) and Edwards & Kumar (1984) that prescribing surveys form a useful part of medical audit, but it seems from this follow-up study that publication of the results of surveys is not enough to overcome the inertia of prescribing habits. Further follow-up studies are needed, associated with planned programmes of information and discussion.

Acknowledgements

We would like to thank Drs A. F. Fairbairn and R. Kumar for their helpful comments and guidance and Mrs P. Place for her secretarial help.

Manic Depressive Psychosis with Mental Retardation and Flexion Deformities:
A Clinical and Cytogenetic Study

A. H. REID, A. J. G. SWANSON, A. S. JAIN, G. SPOWART and A. F. WRIGHT

Five mentally handicapped patients are described in whom a bipolar manic depressive psychosis was associated with flexion deformities, involving principally the fingers. The effect of increasing degrees of retardation on the clinical presentation of the affective psychosis is discussed. Surgical treatment of the flexion deformity brought about considerable improvement in one patient. These five patients were further investigated cytogenetically using high resolution banding techniques. The results obtained were interesting but inconclusive. There would seem to be a definite place for further cytogenetic investigations of some of the more distinctive psychotic disorders using this technique.

One of the authors (A.H.R) has had a longstanding interest in affective disorders in mentally handicapped people (Reid, 1972, 1982), and had been curious to note the development of flexion deformities of the hands in two mentally handicapped siblings in Strathmartine Hospital (mental handicap), both of whom suffered from a bipolar affective psychosis. These flexion deformities had proved remorselessly progressive over the years, despite physiotherapy and even the use of spring-loaded splints.

It seemed possible that the mental retardation, affective disorder and flexion deformities might be causally related, so the authors decided to survey the hands of all the significantly mentally retarded (IQ<50) bipolar manic depressive patients in Strathmartine Hospital to see if they too were affected. In all, five such patients were known to A.H.R. The authors were intrigued to find that each of these five patients showed varying degrees of flexion deformities of the fingers, which had sometimes been misdiagnosed as Dupuytren's contracture. Therefore, we decided to investigate these five patients further by recording the nature and extent of their flexion deformities, preparing a careful psychiatric history and examining their chromosomal findings in some detail. We carried out these chromosome studies in collaboration with the MRC Clinical and Population Cytogenetics Unit in Edinburgh.

Method

Chromosomal preparations were made from cultures of peripheral blood. Extended chromosomes were obtained either by the method of Yunis (1976) or by the method of Ikeuchi (1984) and were G-banded by the ASG method of Sumner *et al* (1971).

Clinical psychiatric and orthopaedic findings

Case 1

Male, aged 58, profoundly mentally retarded, suffers from occasional *grand mal* fits.

This patient can feed himself with a fork and spoon but needs prompting in matters of personal hygiene, dressing and undressing. He has no language but some comprehension.

Prior to admission to hospital at the age of 39 he had been reported as having episodes of restlessness accompanied by insomnia. Since admission he has been noted to have repeated episodes of overactivity, sometimes very severe and accompanied by insomnia, noisiness, unpredictability and aggressiveness, lasting a few days to a few weeks and usually around 1 month. Occasionally these episodes of restlessness are followed by brief periods of unusually quiet, withdrawn behaviour.

At the age of 39, he was described by the physiotherapist as having "excessive tension in many muscles". There were no observable changes at this time but shortly afterwards these began to appear and he has now gone on to develop moderate-to-severe flexion deformities of the middle, ring and little fingers of each hand, with minor involvement of the index finger of the right hand also. In addition there is some limitation of the range of extension of the thumbs on both sides at the metacarpophalangeal joints. There are flexion deformities of the elbows but both wrists have a full range of dorsiflexion and palmar flexion. With the wrists in palmar flexion, it is possible to increase the extension of all the finger joints of the little, middle and ring fingers by some 5–10°. He has little use of his hands but attempts to undo buttons with his thumbs. He can lift objects such as boxes with his thumbs opposing his flexed index fingers and with the wrists held in palmar flexion. There is some wasting of the left leg, involving the calf muscles in particular, but little functional weakness and only a slight diminution of dorsiflexion of the left foot. There is also marked thickening of the outer helix of each ear. There is no evidence of Dupuytren's contracture in either hands or feet and no evidence of Peyronie's disease.

Treatment over the years has included phenothiazines, thiothixenes, butyrophenones, lithium, anticonvulsants and carbamazepine. He is now on carbamazepine 200 mg *t.i.d.*, haloperidol 3 mg *b.i.d.*, procyclidine 5 mg *b.i.d.* and Priadel 1200 mg daily.

Case 2

Female, aged 53, moderately mentally retarded: the sister of Case 1.

She is able to cope with dressing, undressing and most matters of personal hygiene although with some supervision; however, she is persistently inclined to abrade her skin by rubbing it excessively hard with a flannel. Her feeding habits are poor and she tends to bolt her food. In the main she is continent unless mentally disturbed. She is illiterate but able to carry on a rudimentary conversation.

She was described as intermittently sullen and moody at home prior to admission to hospital at the age of 34, but following admission she appeared well settled and posed little in the way of behaviour problems until she was aged 40 when she became quite suddenly quiet, withdrawn, lethargic and hypochondriacal and lost weight. This lasted a few weeks when, over the course of a few days, she displayed a complete change of mood and activity becoming restless, talkative with flight of ideas and an unusual willingness to explore new activities. She expressed wishful fantasies of impending marriage and childbearing. Since then she has shown repeated swings of mood lasting a few weeks to a few months interspersed with periods of normality. When depressed she is described as lethargic, withdrawn, 'confused' and at times preoccupied with thoughts of death or contamination, or with nihilistic ideas of having no clothes. On one occasion she was described as verging on stupor. Manic swings are characterised by restlessness, noisiness, agitation and insomnia. Elation of mood is sometimes present, but more often she becomes excited and the clinical picture is then of a mixed affective state, in which morbid themes and preoccupations co-exist with marked restlessness and impulsiveness. She is sometimes incontinent during episodes of affective disorder.

At the age of 40 she was described as having some 'stiffness' of the fingers. There were no observable changes at the time, but at the age of 47 these were noted to be developing and she was referred for an orthopaedic opinion. She has now gone on to develop flexion deformities affecting particularly the little and ring fingers of the right hand, the index and middle fingers of that hand to a lesser extent, and recently also the little finger of the left hand. In addition, there is some limitation of the range of extension of the right thumb at the metacarpophalangeal joint of the order of some 20°. The wrists and elbows are fully mobile and there is no evidence of Dupuytren's contracture in either hands or feet. Repeated attempts have been made over the years to prevent the development and progression of these finger deformities with help from orthopaedic surgeons, physiotherapy and a variety of spring-loaded splinting devices, all to no avail. She has also had for many years a smooth, non-toxic goitre, not requiring thyroid supplements and antedating the prescription of lithium.

It was felt that she might benefit from surgical lengthening of the common tendons of the flexor digitorum sublimis group and this was carried out via a longitudinal incision in her right forearm. Post-operatively, a considerable increase in extension of the distal and proximal interphalangeal joints of the right hand was achieved.

Treatment over the years has included phenothiazines and butyrophenones, to which she has developed marked side-effects including rigidity and drooling, all of them ceasing on reduction of medication to a low level. She has also had one episode of jaundice which was thought to be due to phenothiazine sensitivity. She was treated with lithium between 1973 and 1979, but this was discontinued because it did not appear to be effective in controlling mood swings and there was concern about its effects on her goitre and renal function. She has also had tricyclic antidepressants as required and two short courses of ECT when at the bottom of a depressive mood swing. She is now on chlorpromazine 25 mg *b.i.d.* and benzhexol 2 mg *b.i.d.*

Case 3

Male, aged 58, severely mentally retarded.

This patient was admitted to Strathmartine Hospital at the age of 11. He is clean, toilet-trained and able to feed and dress himself to some extent. He has a few words but cannot communicate meaningfully.

At the age of 24, he was described as catatonic with *flexibilitas cerea*, and thereafter he went through a phase of negativism and food refusal during which it was difficult to sustain his weight. Around the age of 40, he began to have episodes of noisy, restless, active behaviour, lasting from a few days to a few weeks and accompanied by disturbed sleep. In these episodes, he chatters away volubly in disconnected words, apparently devoid of any communication component. He appears elated in mood and he can become very excited indeed, and latterly aggressive. At other times, he is reported as having had episodes in which he is quiet, passive, withdrawn and unemotional.

In earlier years, he was noted to have particularly long, thin and mobile fingers and toes, suggestive of Marfan's syndrome but with no other symptoms of that disorder. At the age of 55, he was noted to be holding his left arm and hand in an unusual, 'stiff' posture: this proved persistent and progressed rapidly to involve the right arm and hand. He was referred for neurological and orthopaedic opinions, and a variety of medications, physiotherapy and splinting was suggested but to no avail. The flexion deformities progressed rapidly and he has now gone on to develop severe and virtually fixed flexion of the fingers of both hands, with palmar maceration due to the finger-nails digging in. A small degree of passive extension of the little finger is possible and both thumbs are freely mobile. The patient tends to hold his wrists in palmar flexion but passive dorsiflexion is possible with difficulty. There is some flexion deformity of the elbows but the degree is hard to assess. There is no evidence of Dupuytren's contracture in either hands or feet, and no evidence of Peyronie's disease. He is very uncooperative with examination of his hands, and thus no detailed measurements were possible.

Treatment over the years has included phenothiazines, butyrophenones, lithium and carbamazepine, the latter prescribed in an endeavour to control restlessness (Reid *et al*, 1981). He is now on lithium carbonate 800 mg and carbamazepine 500 mg, each at 8 p.m., with an as-required dose of chlorpromazine 100 mg which is hardly ever used.

Case 4

Female, aged 46, moderately mentally retarded.

This patient is competent in most matters of self-care skills within a protected setting and can communicate verbally in a childish way.

She had fits in childhood and adolescence but has had none since the age of 14. She was exploited sexually in earlier years and was admitted to hospital at the age of 17. She is a friendly woman but rather impulsive and quick-tempered. At the age of 28, she had an episode of depressive psychosis in which she appeared depressed, quiet and sullen. She was hypochondriacal and unpredictably aggressive towards nursing staff. Around 1 year later, she became acutely mentally disturbed, restless, talkative and expressing grandiose and wishful delusions of a sexual and pregnancy nature. She entertained the belief that she knew everything, could teach the doctors and nurses and was possessed of great wealth. She claimed to be in communication with God. Her sleep was disturbed with very early morning wakening. This episode of hypomania subsided but subsequently there have been further episodes of affective disorder, although mood swings have been very much less since she was started on lithium in 1971.

On examination of her hands, she has no measurable flexion deformities. However, with the hands held in the position of prayer with the fingers dorsiflexed, there is a clear tendency for the fingers to curl into minor flexion such that the palmar surfaces of the fingers cannot be approximated. There is also the impression of some tightness of the long flexors.

In earlier years, she was treated with phenothiazines, antidepressants, one course of ECT and butyrophenones as appropriate for episodes of affective disorder. Since 1971 she has been maintained on lithium carbonate which has been substantially successful in controlling her affective disorder. Her present medication consists of haloperidol 3 mg *t.i.d.*, benzhexol 4 mg *t.i.d.* and lithium carbonate 500 mg *b.i.d.*

Case 5

Female, aged 57, moderately mentally retarded, suffers from very occasional *grand mal* fits.

This patient is competent in most matters of self-care skills within a protected environment.

She was exploited sexually in earlier years and was admitted to hospital at the age of 26. At the age of 29 she was recorded as having episodes of noisy, quarrelsome behaviour, but her first episode of clear affective illness as such was at the age of 37, when she was described as restless, noisy, elated and talkative for around 4 months, swinging down to a state of quite severe depression with disturbed sleep, early morning wakening, emotional lability and aggressiveness. There was a further episode lasting a few weeks at the age of 41, in which she was restless, noisy, irritable and impulsively aggressive, again followed by a clear depressive downswing with emotional lability, much crying, psychomotor retardation and disturbed sleep. There have been further similar episodes of affective illness over the years and these continue up to the present.

On examination of her hands, she has no measurable flexion deformities but again, with the hands held in the position of prayer, there is a clear tendency for the fingers to curl into minor flexion, such that the palmar surfaces of the fingers cannot be approximated. There is also the impression of some tightness of the long flexors.

Treatment over the years has included phenothiazines, butyrophenones and antidepressants as required for episodes of affective disorder. Since 1971 she has been on lithium carbonate which has been partially successful in controlling her manic depressive psychosis. Her present medication consists of chlorpromazine 50 mg *b.i.d.*, prothiaden 75 mg *nocte* and lithium carbonate 500 mg *nocte*.

The clinical data on these five patients are summarised in Table I and the degrees of the flexion deformities and the results of surgical treatment in Table II.

TABLE I
Clinical data on the five patients

Case	*Sex*	*Retardation range*[1]	*Epilepsy*	*Approximate age at onset of flexion deformities (to nearest 5 years)*
1	M	Profound	Grand mal	40
2	F	Moderate	—	45
3	M	Severe	—	55
4	F	Moderate	In childhood and adolescence	45
5	F	Moderate	Grand mal	55

1. According to ICD-9 (World Health Organization, 1978).

Cytogenetic analysis

G-banded extended chromosomes were examined in all five cases. One observer considered that three of the cases showed a difference between homologues in the region 2q22.1 to 2q24.1. Further examination by other observers led to the conclusion that the differences observed were not inconsistent with the variation observed in control cases. The two other probands showed no abnormality.

TABLE II

Degrees of flexion deformity (0° = full extension)

Discussion

These five patients, only two of whom are related, appear to share some features in common. Firstly, they are all very significantly mentally retarded and in each case the retardation is of unknown origin and appears to be congenitally determined. The presence of such associated phenomena as minor congenital abnormalities in Case 1, and of *grand mal* epilepsy in Cases 1, 4 and 5, is in keeping with this conclusion.

Secondly, all five patients suffer from an associated psychotic illness clinically suggestive of a bipolar manic depressive psychosis. The diagnosis of manic depressive psychosis can be difficult in mentally retarded patients, particularly in those with more severe degrees of handicap such as Cases 1 and 3. In Case 1, however, there was a family history of manic depressive psychosis affecting his sister (Case 2) and, in addition, another younger brother of dull/normal intelligence suffered from a bipolar manic depressive psychosis. This younger brother lived independently, ran the family farm and had been admitted to inpatient psychiatric care in a different hospital in a different catchment area on three occasions with episodes of mental illness. These episodes of illness were diagnosed independently as manic depressive psychosis in nature and treated with lithium in the absence of knowledge of the history of mental illness involving his two siblings. Furthermore, the mother of Case 3 had spent many years in a mental hospital and died there, suffering from a mental illness characterised in earlier years by depression and critical auditory hallucinations, although latterly it had been complicated by severe deafness and was regarded as paraphrenic in nature. Finally, the sister of Case 5 also had a history of affective disorder, treated independently with ECT in another hospital. Therefore, we feel that, notwithstanding the difficulties in diagnosing affective disorder in retarded patients, a good case can be made out for suggesting that these five patients were suffering from a bipolar affective disorder.

Thirdly, these five patients also suffered from flexion deformities of varying degrees involving the fingers in all cases, the thumbs in Cases 1 and 2 and the elbows in Cases 1 and 3. These flexion deformities were associated with a sensation of 'stiffness' or 'tightness' in the long flexor muscles of the fingers. This stiffness had been noted in Cases 1 and 2 some years prior to the onset of obvious flexion deformities. Some of these flexion deformities had been described, wrongly, as Dupuytren's contractures in the notes. Dupuytren's contracture is a pathological condition of the palmar fascia and cannot be overcome partially by flexion of the wrist, or by a flexor tendon lengthening operation in the forearm. These flexion deformities were certainly of variable severity. In Cases 4 and 5, the deformities were mild and possibly of arguable significance, but in Cases 1, 2 and 3 they were obvious, gross and caused considerable nursing problems in relation to feeding, dressing and hygiene. This tendency towards flexor hypertonus is one of the features that Rogers (1985) remarked on in his comprehensive and scholarly review of the motor disorders of severe psychiatric illness. He concluded that these motor disorders lead one inescapably to the unfashionable conclusion that severe psychiatric illness is regarded most appropriately as a form of neurological disorder, and he casts doubt on psychogenic and institutional theories.

There is the possibility that these flexion deformities were drug-induced and related to the prescription over years of phenothiazines, butyrophenones, anticonvulsants or lithium. However, if that is so, it is difficult to explain why they developed in these five patients and not in so many other mentally retarded patients, who were also treated with phenothiazines or butyrophenones but did not suffer from manic depressive psychosis. An increased incidence of Dupuytren's contracture has been reported in epileptics, and Critchley *et al* (1976) suggested a link with long-term phenobarbitone treatment. In the five cases in the present series, however, the deformities were not typical of Dupuytren's contracture, and in two of the cases there was no history of fits. Moreover, these two cases included both the most severely affected patient (Case 3) and one member of the sibling pair (Case 2). There is nothing in the literature to suggest that lithium induces flexion deformities, but it is the one drug these five patients did have in common. However, a survey of 100 consecutive attenders at the lithium clinic in Dundee showed only one hand deformity, and that was traumatic (S. E. Hopwood, personal communication). Therefore, we feel it is unlikely that either phenothiazines, butyrophenones, anticonvulsants or lithium preparations were instrumental in promoting these flexion deformities.

Thus, it seemed that in these five cases, the diagnosis of idiopathic mental retardation, sometimes accompanied by idiopathic epilepsy, manic depressive psychosis and flexion deformities might be meaningfully linked. This was an intriguing possibility and we sought through chromosomal studies to see if a chromosomal marker could be identified.

With the advent of high resolution banding (HRB) techniques, it has become possible to identify up to 850 bands in human chromosomal preparations obtained at the prophase or prometaphase stages of mitosis (ISCN, 1985). This has significantly increased the resolution of cytogenetic techniques for the identification of chromosomal aberrations giving rise to genetic abnormalities. Therefore, HRB studies were used to identify chromosomal aberrations in this sample of patients. The techniques are time-consuming and require considerable expertise, but it was considered important to exclude abnormality at this level of resolution, since the identification of such an abnormality could lead to the localisation of a major gene conferring susceptibility to affective disorder. Genes responsible for retinoblastoma, Wilms' tumour, Duchenne muscular dystrophy, chronic granulomatous disease and other diseases (HGM8, 1985) have been localised following the identification of specific aberrations in this way. In the case of affective disorders, where there is a relatively high general population frequency (*c.* 0.1% for bipolar disorders), the coincidence of a chromosomal aberration with the clinical abnormality could arise by chance. This might occur in about 0.1% of all mentally handicapped individuals, if the two conditions are unrelated. Alternatively, the existence of patients exhibiting both clear-cut cyclical manic-depressive mood swings, together with non-specific features such as mental handicap and/or dysmorphism that are found almost invariably in patients with moderate-sized chromosomal deletions and unbalanced rearrangements, might imply deletion (and loss of function) of a major gene responsible for affective disorder, in addition to loss of other genes causing non-specific developmental abnormality.

There is considerable evidence for the existence of genetic factors in bipolar illness (Gershon, 1983), which is consistent with the presence of a major gene influence showing reduced penetrance (O'Rourke *et al*, 1983). In the case of the patients studied here, there is a third common factor, namely the occurrence of delayed onset, progressive flexion deformities affecting the hands and forearms to varying degrees. This condition has not been described as a specific genetic syndrome either on its own, or in combination with the other features observed here. It could be postulated either that these are pleiotropic effects of a single, rare mutant gene or that they are all consequent on the simultaneous loss of large numbers of linked genes due to deletion of a chromosomal segment. Visible deletions probably only represent a small proportion of all deletions (see Vogel & Rathenberg, 1975), many more of which are now being detected at the DNA level by means of gene probes (Monaco *et al*, 1985). Although some variation in the dark G-bands was observed in three of the patients in a region of chromosome 2 (2q22.1-2q24.1), it was felt that this degree of variation was not outside the range of variation seen in normal controls. This emphasises the difficulty of positively identifying small deletions using HRB, where small differences in the degree of contraction of G bands can occur even between apparently normal chromosomal homologues. Some of the variation of this sort may be of a heritable nature, representing banding polymorphisms; in other cases, it may be due to small differences in the rates of condensation of chromosomal homologues during the progression from prophase to metaphase.

Therefore, our chromosome studies were unfortunately inconclusive. However, we do feel that this technique could be of very substantial potential interest in psychiatry, particularly in the investigation of the more distinctive and identifiable psychotic disorders, and further studies would be very worthwhile.

Addendum

It has just come to light that the sister of Case 4 suffers from a bipolar manic depressive psychosis, independently diagnosed and treated with lithium in another hospital in the absence of knowledge of the relationship. She is also mentally retarded and said to have the same incurving fingers with inability to approximate the palmar surfaces.

Acknowledgements

We acknowledge the help of Miss K. Buckton in examining the chromosome preparations and of Dr D. Tait for psychiatric diagnostic information about the brother of Cases 1 and 2. We are also grateful to Dr S. E. Hopwood for the information about the lithium clinic attenders.

The Influence of Depression on the Processing of Personal Attributes

P. I. CLIFFORD and D. R. HEMSLEY

Depressed, schizophrenic and normal subjects were tested for incidental recall and recognition of lists of positive and negative personal attributes. It was hypothesised that depressives would show a deficit in recall and recognition of words of which they had been asked a self-referential encoding question, but would show equivalent performance to controls on words of which they had been asked an other-referential, semantic or structural encoding question. The experiment was designed to enable a decision to be made between two possible explanations of the expected deficit: Davis's (1979) suggestion that it is due to disorganisation of the self-schema in depression, and the hypothesis of Beck *et al* (1979) that depression is characterised by the predominance of a negative self-schema. The expected deficit was observed on the recall but not on the recognition task. However, the precise pattern of the results raises problems for both of the above interpretations, and alternative explanations are considered.

There has been a growth of interest in the role of cognitive processes in psychological disorders, stimulated on one hand by the emergence of cognitive theories of clinically observed phenomena, such as Beck's (1967) theory of depression, and on the other by attempts to apply information-processing models to the deficits or symptoms observed in clinical populations (e.g. Hemsley, 1982). The present study investigated the processing of personal attributes by depressed patients, attempting to clarify the role of depressives' self-schema in their psychological functioning.

There has been a number of attempts to relate cognitive functioning to a psychological theory of depression, Beck's being the most influential. The central premise is that the personal paradigm of the patient when he is in a depressed state produces a distorted view of himself and his world (Beck *et al*, 1979). Distortion is of a negative kind such that persistent negative evaluations are made of the self, world and future. Negative affect is explained as a consequence of negative cognitions, and other depressive deficits, such as in motivation or concentration, are regarded as secondary to the primary cognitive dysfunction. Thus, according to Beck, the depressive subjects incoming information to a systematic schema-mediated processing bias, the self-schema being the origin of such bias.

Beck's concept of the self-schema is similar to that put forward by Rogers *et al* (1977), especially in its implication that the self is active in at least some forms of information processing. Rogers *et al* (1977) set out to investigate "the construct of self and how it is implicated in the organisation of personal data". The self was defined as "an abstract representation of past experience with personal data", which is "activated when a person encounters a situation involving personal information, becoming part of the available information-processing system". To test this they adopted Craik & Lockhart's (1972) proposal that there is a hierarchical organisation of levels of processing, and that the 'depth' of such processing predicts memory trace strength and, in turn, retention, applying this to verbal information. Lockhart *et al* (1976) suggested that the physical, phonemic and semantic characteristics of words exist in what Sutherland (1972) refers to as different domains "proceeding from shallow structural domains to deep semantic domains". A domain in which the self-concept is active is therefore 'deep' in two senses: first, that it is higher in the hierarchy than physical or phonemic domains and, secondly, that *within* the set of semantic domains it would be expected to be of particular significance. To test this, Rogers *et al* (1977) required subjects to encode personal adjectives under different orienting conditions, using a variant of the incidental recall paradigm (Craik & Tulving, 1975). The self-referential question (i.e. describes you?) produced superior recall to the other three encoding questions (semantic, phonemic and structural). They claimed that "involvement of the self in the interpretation of new stimuli imparts a degree of fullness and richness to the input" and that during recall "subjects probably use the self as a retrieval cue'' (Rogers *et al*, 1977). A later study (Rogers *et al*, 1979) employed a similar recognition task, exploring the possibility that the earlier results were not a function of the self-schema but simply an effect of the involvement of a person in the rating task. Though not unambiguous, they concluded that different processes occur in self- and other-referential coding and therefore that the concept of the self-schema is justified.

Other investigators have implicated the self in information processing (e.g. Markus, 1977; Bower & Gilligan, 1979) and for a long time personal construct theorists have had a concept of the self-schema similar to that proposed by Rogers *et al*. However, the first study to employ the methodology of Rogers *et al* (1977) within a clinical population was reported by Davis (1979). He argued that not all depressives respond according to a negative self-schema. Noting that some depressed patients describe themselves inconsistently, he proposed that these had a less well integrated self-schema, comparable to the subjective phenomenon of uncertainty about the self. Davis's (1979) findings demonstrated that depressives' recall was significantly worse on the self-referential coding task than that of the controls, although their performance was equivalent on the other tasks. A problem with the study is that, of the 48 personal attributes employed in his study, 31 were rated by 10 colleagues of the present authors as positive. Hence depressives' performance might be attributable to their tendency to screen out positive input related to the self. A more balanced list, as was to be employed in the present study, could have resulted in equivalent recall on the self-referential question for depressives and controls.

It might also be the case that, irrespective of whether the attributes were regarded as self-descriptive, depressives would have a tendency to recall predominantly negative words, as found by Bradley & Mathews (1983). Most experiments have inferred an adjective's self-descriptive status from a 'yes' response in the self-referential coding condition. This prejudges the issue of whether the self-schema is in fact involved in recall. However, if the operation of the self concept were a major factor influencing recall, one would expect more negative self-descriptive words to be recalled than negative non-self-descriptive words for the depressives, and the converse for the control group. To assess this, the present study required that subjects rate all the words on the list presented, according to a self-descriptive question, after completing the recall task. One can then examine the words recalled to see if more self-descriptive words are recalled than expected by chance. On Davis's theory, since depressives are characterised by ''non schema based responding'', a self-schema effect would not be predicted for the depressives, whereas on Beck's theory it would be dependent on whether the words were positive or negative. A lack of self-schema effect for both groups would challenge both Beck's and Davis's theories, since they agree in implicating the self-schema in non-depressed responding, and only disagree on its role in depressed responses.

There were three further extensions to Davis's study: first, the addition of a recognition task similar to that employed by Rogers *et al*; secondly, the inclusion within this task of both other- and familiar other-referential questions; thirdly, the inclusion of a clinical control group. A sample of schizophrenic patients was assessed in view of several authors' theories of the nature of the self-schema in schizophrenia (e.g. Laing, 1960).

Method

All subjects were to carry out two tasks, one involving recall, the other recognition. For the recall task, three forms of coding were to be employed, for the recognition task four forms.

Materials

A set of positive and negative personal attributes was generated. From this set a subset consisting of half positive and half negative attributes was selected for each of the tasks. The subset was then ordered in a number of ways corresponding to the number of forms of questions being presented in each task and a question order was assigned, each word having each question asked of it on only one of the lists.

The recall list consisted of 24 words, the recognition list of 32 words. In addition, 64 distractor words were required to construct the lists from which subjects were to select the words they recognised. To construct the word lists, a group of 20 psychology students were asked to rate 150 personal attributes as either good, bad or uncertain, and in addition to describe whether it was of long, short or medium length. The recall task set comprised six short positive, six short negative, six long positive and six long negative words. The recognition task set consisted of eight of each of these categories, and the distractor set of these 32 words plus 32 positive and 32 negative words.

For the recall task lists, three word orders were generated randomly. Each word was then assigned one of the three coding questions for each list, such that on any one presentation of a particular list, each coding question would be presented eight times, four times to positive words, and four times to negative words. This was done in such a way as to obviate any possible order effect.

The recognition task list was drawn up in a similar way, except that four word orders were generated. Four recognition distractor lists were constructed of 24 words each. Each consisted of eight words from the list to be remembered (four positive and four negative) and 16 distractor words (eight positive and eight negative).

Coding questions

The coding questions used for the recall task were:

(1) Does the word . . . describe you? (*self-referential question*)

(2) Would you expect a 7-year old child to understand the meaning of . . .? (*semantic question*)

(3) Is the word . . . a long word? (*structural question*)

For the recognition task, questions 1 and 2 from the recall task were employed, plus:

(4) Does the word . . . describe your mother? (*familiar other referential question*)

(5) Does the word . . . describe the person in the photograph? (*photograph of smiling woman; unfamiliar other question*)

Subjects

Subjects were 12 depressed patients, 10 schizophrenic patients and 12 normal controls. The clinical samples were drawn from the Maudsley, Bethlem, St Giles and St Francis Hospitals, London. All but two of the depressives were inpatients. All depressed subjects had received a primary diagnosis of non-psychotic depression and scored more than 20 on the Beck Depression Inventory (BDI) (Beck, 1967). They had an average age of 41.9 years, and a mean BDI score of 31.6. The schizophrenic subjects had a primary diagnosis of schizophrenia, had exhibited first-rank symptoms and had to score below 15 on the BDI. They had an average age of 33.8 years and a mean BDI score of 8.0. The normal controls had an average age of 28.2 years and a mean BDI score of 2.9. No subject had received ECT, showed any signs of neurological abnormality or had a history of alcohol abuse. All subjects completed the Schonell Graded Word Reading Test, and were excluded if scoring less than 58. This test correlates with intelligence (Nelson & McKenna, 1975). Group characteristics, including IQ scores were derived from the tables provided by Nelson & McKenna. The groups did not differ significantly on IQ.

Procedure

Subjects were told that the author was carrying out research on "the way people understand the meanings of words". If they agreed to participate in the study, the Schonell reading test was then administered, it being explained that the subject was to be required to read some words, and that this was a preliminary to ensure that they would be able to do so. Subjects were then presented with the list of words for the recall task. They were given the following instructions: "In front of you is a list of words. I shall be asking you one question about each word, and I would like you to circle a yes or no answer for each word. You may find it hard to decide upon your answer in some cases, but I would still like you to make a definite choice. After I have asked you each question, I would like you to wait until I signal before circling your answer, and then do so promptly. After completing the questions I shall be asking you some more questions about the words on the list." One question was then asked aloud about each word, the experimenter pausing for 3 s after finishing the question before signalling to the subject to circle their response. Once the list was completed, the experimenter turned it over and said, "Now the next thing I would like you to do is to write down as many of the words on that list as you can remember. You have plenty of time. Don't worry about spelling." Subjects were then given 4 min to think of words. The answer sheet was then turned over to its original position, and subjects told: "The final thing I'd like you to do with the list of words is to tick those words that you think definitely describe you. If you are uncertain then miss the word out." This completed the recall task.

Subjects were then presented with the recognition task word list. They were told: "Here is another list of words. We shall be doing the same kind of thing as with the previous list, except that some of the questions will be slightly different, and so will the questions at the end". The photograph was then put next to the word list, the experimenter explaining that "some of the questions will be about the person in this photograph".

Once the coding questions were finished, the list was taken away and the experimenter continued: "This time, rather than asking you to remember words directly, I've four lists of words here. Each list contains some words from the last list and some new words that weren't on either that list or the first list. Indicate those that were on the last list." Subjects were then presented with the four distractor lists in varying orders across subjects, in case later lists tended to have fewer words selected than earlier ones. Finally, subjects were re-presented with their original answer sheet, and asked to tick those words that described them, as in the previous task.

Subjects then completed the Beck Depression Inventory.

Results

Recall task

Results from the two-way analysis of variance are presented graphically in Fig. 1. Overall, these showed significantly

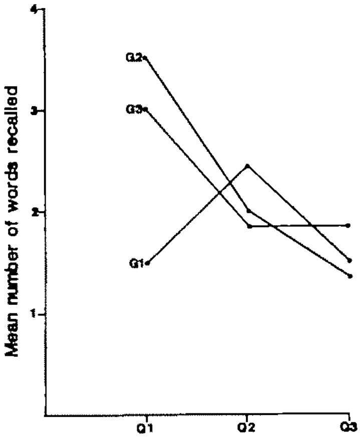

FIG. 1 Group × question interaction (recall task).

TABLE I
Recall task: Group × variable one-way ANOVA

Variable	*G1 Mean*	*G2 Mean*	*G3 Mean*
Self-descriptive positive words recalled	1.7	1.9	2.3
Self-descriptive negative words recalled	0.9	0.9	0.6
Total self-descriptive words recalled	2.6	2.8	2.9
No. of positive self-descriptive words	5.5	6.7	8.3
No. of negative self-descriptive words	5.0	2.7	1.4
Total self-descriptive words	10.5	9.4	9.7
Positive words recalled on self-referential question	0.7	1.8	1.7
Negative words recalled on self-referential question	0.8	1.6	1.3
Total positive words recalled	2.7	2.9	3.2
Total negative words recalled	2.6	3.3	3.4

enhanced recall for the self-referential condition ($P<0.01$, $F=6.639$). Depressives recalled fewer words of which they had been asked the self-referential question than did the other groups ($P<0.01$, $F=5.1$), but showed equivalent recall on the semantic and structural questions.

Analysis of the data of Table I revealed the following:

(a) Depressives selected as self-descriptive fewer positive words ($P<0.06$, $F=3.1$) and more negative words than did controls ($P<0.002$, $F=11.4$).

(b) Depressives recalled as many self-descriptive words as did the control groups, and there was no tendency for any group to recall more self-descriptive words than non-self-descriptive.

(c) Depressives showed no tendency to recall proportionately more negative self-descriptive words, nor did controls show a disproportionate bias towards positive self-descriptive words.

(d) Depressives showed no tendency to recall negative rather than positive words for the task as a whole.

(e) Depressives showed no tendency to recall negative rather than positive words in relation to the self-referential question.

(f) Depressives recalled fewer positive words on the self-referential question than controls ($P<0.001$, $F=7.2$). There was also a (non-significant) tendency to recall fewer negative words ($P<0.2$, $F=1.8$).

There was no tendency for any group to remember more words to which 'Yes' replies were given.

Recognition task

The results of the two-way analysis of variance are illustrated in Fig. 2. The self-referential question resulted in higher recognition scores for all groups ($P<0.01$, $F=8.5$). This is in marked contrast to the depressives' deficit on the recall task under this coding condition.

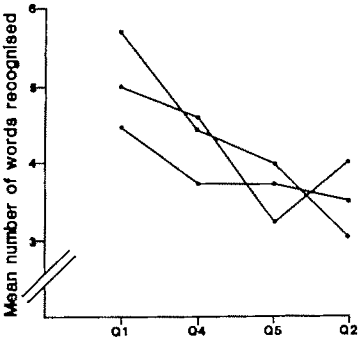

FIG. 2 Group × question interaction (recognition task).

The univariate analyses produced a similar pattern of results as on the recall task and hence will be mentioned only briefly. Depressives recognised as many self-descriptive words as did the control groups. There was no tendency for depressives to recognise only negative words on the self-referential question. Although there was no difference between groups in the number of positive or negative words recognised, depressives did make more negative 'false alarms' than the other groups made ($F=9.6$; d.f. 2, 31; $P<0.001$). The groups did not differ significantly on the number of positive false alarms. Although a signal detection theory analysis of these last finds was considered, it was felt that the assumptions necessary for its application were not necessarily justified for the present task.

Discussion

As expected, the control subjects recalled significantly more words related to the self-referential question than to the semantic or structural question. This is consistent with the original findings of Rogers *et al* (1977). Similar findings for the control subjects are apparent on the recognition task.

The pattern of results for the depressed subjects is somewhat different. As in Davis's (1979) study, on the recall task depressives recalled significantly fewer words of which they had been asked the self-referential question, compared to both control groups, but showed equivalent performance on the semantic and structural questions. Although this group difference was somewhat greater for positive words on the self-referential question, the trend was also apparent for negative words. This is in contrast with the findings of Derry & Kuiper (1981), who claimed that the expected enhanced recall under the self-referential condition was apparent for depressives if depressed content adjectives were employed.

On the recognition task, depressives showed no deficit on the self-referential question. However, while positive 'false alarms' were made equally often by the depressives and normals, negative 'false alarms' were more common in the depressed group. Dunbar & Lishman (1984) found no such difference but did report a higher 'hit rate' for negative words in their depressed group relative to controls. The latter authors carried out a signal detection analysis in an attempt to clarify their findings. As noted above, this was not done here, as it was felt to depend on assumptions whose validity for the present experimental task remains to be demonstrated.

It could be argued that depressives' differential pattern of performance on recall and recognition tasks is because only the recall task required the use of the self-schema as a retrieval cue. However, it is clear that there was no tendency for any group to recall or recognise proportionally more words that were regarded as definitely self-descriptive as opposed to those words that were not. This is hard to reconcile with the theory of Rogers *et al* (1977) that it is the self-schema which is active in producing enhanced recall for the self-referential question. By the same token, Davis's theory that depressives' deficit on recall is due to disorganised self-schema relative to that of non-depressed subjects fails to receive confirmation, since it also depends on the assumption of an observable self-schema effect on non-depressed recall of self-descriptive words. Thus, although the self may indeed be functioning in initial processing, it does not seem to be implicated in retrieval in the way proposed.

Nor are the data clearly supportive of the hypothesis suggested by Beck's theory, that depressives' recall deficit may be due to a negative response bias. His general theory receives some support from the depressives' self-image being significantly more negative, and their tendency on the recognition task incorrectly to select negative words as having been on the original list more often than controls. However, its application to the effect under consideration is questioned by the lack of a tendency for depressives to recall more negative words, their failure to recall proportionately more negative self-descriptive words than positive self-descriptive words, and the lack of a tendency for them to recall more negative words than did the controls in relation to the self-referential question.

Therefore, the data do not clearly support either Davis's or Beck's account of the replicated depressive deficit on the self-referential recall task. The absence of this effect and the greater number of false alarms on the recognition task also have to be explained. Rather than using the self-schema as a cue in retrieval, as suggested by Rogers *et al*, it is possible that in order to recall the self-referential question words, the subject uses the self-referential *question* as a cue. This effectively requires 'thinking about himself'—for a depressed person a process that may act simultaneously as a cue for negative affect and/or a distraction from the recall task on to a stream of automatic, negative thoughts, as suggested in Beck's theory. In other words, the subject may be diverted from the goal of retrieval because the retrieval cue also cues other processes. This could also explain the tendency to perform worse on recall of positive words, since it is plausible that negative affect is more likely to interfere with the recall of positive attributes than negative ones. The lack of differential performance on the recognition task is explained because there is not the same need for a retrieval cue as the words are already present. Also explained is the greater number of negative false alarms for depressives than for controls, since negative affect is likely to make negative items seem more congruent with the subject's experience than positive ones, and therefore seem more familiar.

The problem remains of reconciling the lack of self-schema effect for all groups with the enhanced recall of controls on the self-referential coding condition. One answer is to make the intuitive distinction between the self and the self-schema, the latter being defined as a representation of the former. In accordance with the depth of processing model, one could then agree with Rogers' claim that involvement of the *self* imparts greater richness to the input, and therefore that memory trace strength as measured by recall would ordinarily be enhanced, but dispense with the view that the *self-schema* is used as a retrieval cue. This would explain the key finding that recall performance and self-descriptiveness appear to act independently.

Brief Reports

Neuroleptic Malignant Syndrome Superimposed on Tardive Dyskinesia

A 30-year-old man with a 3-year history of tardive dyskinesia developed a neuroleptic malignant syndrome while having reserpine and lithium; his symptoms worsened following three doses of neuroleptic medication and improved with bromocriptine. The pre-existing dyskinesia made the presentation confused, and delayed proper diagnosis.

Neuroleptic malignant syndrome (NMS) is an acute and sometimes fatal complication of neuroleptic medication, characterised by muscle rigidity, hyperpyrexia, and mental confusion; it appears to be caused by alterations in dopamine neurotransmission in the basal ganglia and the hypothalamus. Its relationship to other neuroleptic-induced movement disorders such as dystonia, parkinsonism, and tardive dyskinesia (TD) remains unclear. We describe here a case of NMS that developed in a patient with pre-existing TD; to the best of our knowledge, this is the first report of such an association. The concurrence of these two syndromes in this case delayed the recognition of NMS, and led to treatment strategies that may have exacerbated it.

The Case

Mr A, a 30-year-old white male with a history of recurrent paranoid psychosis, was referred to our inpatient service for treatment of severe TD of approximately 3 years' duration. He had taken neuroleptic medication, including thioridazine, oral and depot fluphenazine, and trifluoperazine continuously for 7 years. His abnormal movements began in his tongue, and slowly progressed to involve his head, neck, trunk, and lower extremities. His family noted episodes of severe diaphoresis and hyperpyrexia, but was unable to measure his temperature. Approximately 1 month prior to admission, neuroleptics were discontinued, and lithium and diazepam initiated; psychotic symptoms were well controlled on this regimen.

On admission, the patient was observed to have severe choreoathetoid movements involving all four extremities, spasms of his neck and back muscles, twisting movements of his neck and trunk, grimacing, and occasional grunting; EEG, CT scan, and ceruloplasm were normal. Serum LDH was slightly elevated. There was no family history of movement disorder. Lithium (900 mg/day; serum level 0.6 meq/litre) and diazepam (30 mg/day) were continued.

Reserpine was begun at 0.25 mg/day and was slowly increased over a 2-week interval to 1.25 mg/day. Initially he appeared to benefit, exhibiting a relative decrease in trunkal movements and having improved sleep. However, at doses of 1–1.25 mg of reserpine, his movements became more pronounced, and he developed transient blood pressure elevations to 170/110 mmHg, intermittent diaphoresis, tachycardia, and pallor. Lithium and reserpine were discontinued.

The patient developed intermittent stridor, dysphagia, and auditory hallucinations 5 days after the discontinuation of reserpine, and 3 days after discontinuation of lithium. He was considered to have acutely worsening TD, and was given two 50 mg doses of thioridazine and one 5 mg dose of haloperidol over 24 h. Following each dose, he fell asleep, and became free of movements for several hours. Within 4 hours after receiving haloperidol, he became extremely rigid, and his rectal temperature rose to 104°F. White blood count increased to 24 000, and marked elevations were noted in CPK, LDH, and SGOT. Bromocriptine (5 mg) was administered, producing a rapid (1.5 h) return to normal temperature and a significant reduction in rigidity.

The subsequent course was complicated by the development of acute renal failure secondary to rhabdomyolysis (CPK>99 999U), which required renal haemodialysis. Bromocriptine was continued at a dose of 15 mg/day. Unexplained temperature fluctuation, diaphoresis, and leucocytosis persisted intermittently for 7 weeks, and seemed to worsen whenever bromocriptine doses were withheld. Dyskinetic movements continued at the same level of severity as had been seen on admission, and were unaffected by a trial of lecithin and later increases in the bromocriptine dose to 27.5 mg/day. Three months after the onset of NMS, he was successfully weaned from bromocriptine and was discharged home.

Discussion

Rapid onset of fever, diaphoresis, muscle rigidity, and hallucinosis shortly after neuroleptic administration have been described here in a patient with TD. These symptoms, with the accompanying findings of elevated blood pressure, pallor, leucocytosis, liver function abnormalities, and elevated CPK, are consistent with NMS as described by Cope & Gregg (1983). Rhabdomyolysis and renal failure are not uncommon complications of this disorder (Eiser *et al* 1982). Rapid response to dopamine agonists is also characteristic of NMS (Mueller *et al*, 1983), and further supports the diagnosis in this case.

Our patient's initial symptoms were consistent with TD, and were severe enough to warrant an attempt at pharmacological intervention: reserpine may ameliorate some cases of TD (Klawans *et al*, 1980). Thioridazine and haloperidol were given on a trial basis when the movements continued to worsen, despite the withdrawal of reserpine; this was based on the assumption that we were dealing with worsening TD, and that more complete blockade of dopamine receptors would provide at least temporary palliation. Both of these interventions made sense for TD, but are likely to worsen NMS, which appears to be a syndrome of acute dopamine blockade (Mueller *et al*, 1983). Our assumption that we were dealing with TD alone kept us from pursuing the diametrically opposed, but appropriate strategy of administering a dopamine agonist instead of a dopamine antagonist. When NMS was finally recognised, bromocriptine was administered, with rapid improvement in temperature and muscle rigidity.

Neuroleptic malignant syndrome is usually precipitated by neuroleptics, but can also be induced by other treatments that cause diminished dopaminergic neurotransmission. In our patient, the full syndrome did not become manifest until after a dose of haloperidol, but premonitory signs of autonomic instability and increased muscle tone had actually begun a week earlier, when reserpine dose was increased to 1 mg/day. Thus, we believe that haloperidol simply hastened the process already set into motion by reserpine. Although reserpine itself has not previously been implicated in NMS, there has been a report of NMS associated with tetrabenazine (Burke *et al*, 1981), which has dopamine-depleting effects similar to those of reserpine. Dopamine depletion, which should take longer to reverse than dopamine receptor blockade, may have been the reason why vestiges of NMS persisted considerably longer in this patient than in cases induced by neuroleptics alone. Lithium may interact with haloperidol to produce a syndrome similar to NMS (Spring & Frankel, 1981), but it is less clear that lithium can be implicated in our case, since it had been discontinued 3 days prior to the onset of the full-blown syndrome.

Hot weather may contribute to the development of NMS, or to neuroleptic-related heat stroke, which may mimic NMS. Although our patient's symptoms occurred during the summer months, he was confined to an air-conditioned unit, thus diminishing the likelihood that heat was a causative factor. The findings of diaphoresis and marked increase in CPK are inconsistent with the diagnosis of neuroleptic-related heat stroke.

We cannot tell whether the TD and NMS were related or simply occurred together coincidentally. The reports by the family of transient diaphoresis and elevations of temperature in the months prior to admission suggest that his NMS actually had its onset in a milder form, prior to the severe episode we observed, and that its development paralleled the worsening of the TD. Phenomenologically, NMS appears more similar to acute dystonia than to TD. It is of interest that our patient's TD was atypical, not just in terms of its severity, but also in the preponderance of neck, arm, and trunkal dystonia. In this regard, our case bears some resemblance to those of tardive dystonia reported by Burke *et al* (1982). At present, it is not known whether tardive dystonia is truly distinct from TD in general, or whether it is related to NMS. However, it may be possible that our patient and those described by Burke *et al* (1982) suffered not from typical TD, but rather from a similar, but mechanistically distinct, neuroleptic-related disorder that in some instances can affect autonomic and temperature homeostasis as well as muscle tone.

Not all cases of TD may be at risk for development of NMS, but clinicians should be aware of the possibility of this complication. Reserpine should only be used judiciously in the treatment of TD and is perhaps best avoided in atypical cases. A history of unexplained hyperpyrexia or autonomic instability may help in the identification of those who are more vulnerable to full-blown NMS when exposed to sufficient dopamine blockade.

Koro and Schizophrenia in Singapore

A case of Koro is described in an elderly person with associated inguinal hernia and schizophrenia. Its aetiology and origin are traced in Chinese culture, to the Chin Dynasty. A nosology for the classification of Koro Syndrome is proposed.

Koro is a culture-bound syndrome, characterised by a fear of shrinkage of the genitalia into the abdomen. Its cardinal manifestations are: a belief of retraction of the penis and impending death; a panic syndrome with fear, feeling of collapse, palpitations, sweating, breathlessness, and bodily spasms; complications arising as a result of remedial measures.

In Singapore, Gwee (1968; Koro Study Team, 1969) has traced the fascinating origin of Koro in Chinese culture. The disease was first described in the Yellow Emperor's Book of Medicine in 3000 BC. The cases described had a chronic course, but by the time of the Chin Dynasty, the illness was described as having acute onset, and was associated with sexual activity. In the New Collection of Remedies of 1834, Pao indicated that Koro could be precipitated after sexual intercourse or following exposure to 'cold' or raw food.

In 1969, the Koro Study Team and Ngui reported on an "epidemic" in Singapore. Cases appeared after rumours had spread about some men having Koro after eating pork from pigs innoculated against swine fever. The number of cases rapidly increased, and it became a common sight to see men appearing at admission rooms, with chop-sticks and other mechanical aids tied to their sex organs. The Koro Study Team reported on 450 cases, 95% being young Chinese males; most were of acute onset and brief duration, but 17% had recurrent attacks. Simple treatment measures, such as reassurance and suggestion, were all that was required.

An epidemic of such magnitude is unlikely to occur in Singapore again, due to the rapid modernisation since 1969; isolated cases are probably seen, but not reported. However, in Assam (Dutta *et al*, 1982), and Thailand, epidemics have been reported more recently. It is interesting that very few cases are associated with schizophrenia.

Classification

With a greater number of reports of Koro and Koro-like disorders in both Chinese and non-Chinese subjects, it may now be possible to attempt a classification of the syndrome.

Classical Koro

Koro is common in Chinese people, and has an indisputable cultural origin. It is short-lived, is not related to underlying psychiatric illness, but can be recurrent, and is treatable by simple measures such as reassurance. Epidemics can occur, if enough fear is generated by the spreading of rumours.

Koro grafted upon an underlying psychiatric illness

Koro has a natural history which is different from any underlying illness. It is most likely to be associated with anxiety states and Yap (1965) reported 14 out of 19 cases studied to be suffering from anxiety, but it has been reported also in depression, schizophrenia, and brief psychotic states. It has a cultural basis. Most cases of Koro fall into this category.

Koro as a symptom of mental illness

The Koro symptom is based on a delusion, or is the result of depersonalisation with possible accompanying psychotic states like schizophrenia, and is not culturally determined. It resolves when the underlying illness abates. This is more likely to occur in non-Chinese samples. When associated with mental illness simple measures such as reassurance and education may not be sufficient.

Koro associated with a schizophrenic illness is, however, rare. Yap (1965) described six cases, while a number of Koro-like states have been reported in non-Chinese schizophrenic subjects (Edwards, 1970; Cremona, 1981; Ang & Weller, 1984). We describe here a case of Koro superimposed on an underlying schizophrenic illness.

Case report

Mr X, a 75-year-old widower, emigrated from China to Singapore many years ago; he has one son, who is married with a child. Mr X is an introverted man, with few friends and associates, but fairly independent. At the age of 43, he lost his wife, soon after the birth of a daughter; having no means to care for this child, he had to agree to adoption. He retired from his job as a shop assistant in 1969; the following year, he became depressed and attempted suicide, but did not seek psychiatric treatment.

In 1972 (age 63), he developed a schizophrenic illness, characterised by delusions of persecution, directed at neighbours, and the media (he thought the radio was communicating his thoughts to the neighbourhood). He responded well to trifluoperazine as an inpatient, but relapsed in 1984, with persecutory ideas directed at the police and neighbours. He was treated with promazine as an outpatient. A week later, he appeared at the admission room at midnight, complaining that his genitalia were shrinking into his abdomen, after he had eaten bananas. He was acutely anxious, and feared that the condition could be lethal. As a result, he tied a piece of cloth to his penis to prevent further shrinkage. Physical examination was essentially normal, except for a reducible inguinal hernia; there had been no trauma to his sex organs. He was reassured and counselled about his Koro, and advised to continue with the antipsychotic medication. Despite this advice, however, he stopped the medication after a short period. Mr X's son and daughter-in-law were advised not to reinforce his symptoms, which ceased within a few weeks of onset. He was transferred to a home for the elderly, run by a Chinese Temple, in March 1985. After 6 months he was still deluded about his persecutors, but denied his Koro symptoms with embarrassment.

Over the years, he had become isolated, due to the death of his wife and separation from close neighbours. His vision had also deteriorated. With the appearance of a psychotic relapse, he became house-bound because of his paranoid fears. It was in this context that his Koro appeared. Relevant factors included both cultural beliefs and his physical and psychiatric health.

Discussion

This case had an associated inguinal hernia of a year's duration; its presence probably directed Mr X's attention to the genital area. The Koro Study Team (1969) reported also a case associated with a hernia. This patient also believed that bananas ('cold' food) precipitated the attack, which is consistent with Chinese cultural beliefs as during the Chin Dynasty, it was widely believed that Koro was precipitated either by sexual intercourse of by ingestion of raw or 'cold' food (Gwee, 1970). Though the patient had an underlying schizophrenic illness, many of the features of culture-bound Koro were evident; his psychosis continued after the Koro symptoms resolved, with a high level of anxiety when the psychosis reappeared. It is possible that the presence of anxiety associated with depersonalisation could have further facilitated the appearance of the Koro.

In younger samples, sexual conflicts and personality factors are aetiologically significant, in addition to cultural beliefs (Yap, 1965). The useful analysis by Berrios & Morley (1984) of reports of cases in non-Chinese patients showed that psychosexual conflicts were prominent, but in the elderly, these are unlikely to be relevant.

Though Koro is primarily a disorder of the young, it can nevertheless occur in the elderly: the oldest patient in the Koro Study Team was aged 70. In such cases other diagnostic possibilities such as local or systemic disease, CNS disorders or drug-induced states should be looked for, in addition to psychiatric illness.

A Standardised Assessment of Personality Disorder in Mental Handicap

Forty patients with mild or moderate mental handicap were assessed by two psychiatrists using the scale devised by Mann *et al*, 1981 which describes abnormalities of personality. Analysis by weighted Kappa showed excellent agreement for some items (introversion, hysterical explosive, sociopathic, anankastic and affective). This questionnaire may be useful in the evaluation of personality in the mentally handicapped.

The concept of personality disorder has always presented problems but most psychiatrists find it helpful to use it in their clinical practice. In the field of mental handicap abnormalities of personality can be very important and may be a crucial factor in determining whether an individual can survive independently in the community. There have been various clinical descriptions of personality disorders in mental handicap but few systematic studies, although Corbett (1979) estimated that 25.4% of adults in the Camberwell survey manifested personality disorder.

In general psychiatry there have been several reports describing methods of systematically estimating abnormal personality (Presly & Walton, 1973; Tyrer & Alexander, 1979; Mann *et al*, 1981). Mann *et al* reported on a standardised assessment of abnormal personality using an observer report and showed this to be reliable in a preliminary study in individuals of normal intelligence. The scale contains the personality types in Section 301 of the ICD (1977) with the addition of 'anxious' and 'self conscious'; the personality characteristics 'introversion' and 'extraversion' are also included. The aim of the present study was to evaluate the use of this scale in the assessment of personality disorder in the mentally handicapped.

Method

Forty mentally handicapped patients in Strathmartine Hospital, Dundee were included. The patients were selected randomly from 144 patients with mild or moderate mental handicap in eight mainly long-stay wards of the hospital: 18 males and 22 females were included and the mean age was 48.5 years (range 20–80 years).

Only individuals with mild (14) and moderate (26) mental handicap were studied as it seemed likely that this questionnaire would be less applicable to more handicapped individuals. The diagnosis was taken from the case records and based on the 9th Revision of the International Classification of Disease categories of mild (IQ 50–70) and moderate mental retardation (IQ 35–49). Patients with acute psychotic illness were also excluded as personality may be distorted, particularly by schizophrenia.

The patients were assessed by interviewing the trained nurses in charge of the ward who knew them well. The nurse involved was usually the Charge Nurse with an RNMD qualification and sometimes also an RNM. The two raters were together when the nurses were interviewed: one of the raters (hereafter described in the text as the principal rater) conducted the interview, whilst the other rater acted as an observer. The two raters then assessed the interview independently using the scale described by Mann *et al* (1981).

The schedule of Mann *et al* was designed to reflect the clinical approach of a psychiatrist interviewing a patient's informant. After a general introduction there is an exploratory section where the description of personality is ascertained, followed by seven standard questions if necessary. If certain 'key words' have been used, a series of questions appropriate to one or more personality types is used. The interviewer then records the type and grading of personality. A grade 1 indicates that the personality can be matched by one of the types and a grade 2 that the description indicates that the patient is very unusual or handicapped by reason of this personality. Features of more than one type may be present but the interviewer should establish which is the more dominant.

The results were analysed by the weighted Kappa method (Cohen, 1968) which provides a measure of agreement between raters. The advantages of this method are that it takes into account chance levels of agreement by the judges and allows credit for partial rater agreement.

Results

Table I describes the personality disorders and characteristics scored by the principal rater, together with the Kappa results using the scores of both raters. Agreement is recorded as being excellent (Kappa values over 0.75) for some items (introversion, hysterical, explosive, sociopathic, anankastic, affective) and fair (Kappa values 0.40–0.59) for others (self-conscious, extraversion) (Cicchetti & Sparrow, 1981). The types schizoid, paranoid, anxious and asthenic were only rated once or not at all.

Ten of the 40 patients were not rated by the principal rater as showing any particular personality types. Of the remainder 17 were rated as having one personality type, 11 as showing two and two as showing three personality types. Mann *et al* (1981) recommended that where this occurs in clinical practice, the dominant personality type should be identified and recorded. Since the present study

TABLE I

Personality type 40 patients	*Grade I*	*Grade II*	*Total grade I and II*	*Weighted kappa*
	(principal rater)			
Extraversion	4	0	4	0.5460

*Insufficient ratings for analysis
The principal rater is the rater conducting the interview although results recorded by both raters are used in calculating the weight Kappa.

was aimed at assessing reliability, however, we used all the available data to provide the broadest possible base from which to draw conclusions.

Discussion

The present study only assessed inter-rater reliability and it is not possible to comment on test–retest reliability or validity. The fact that the same interview was used by both raters for practical reasons is also a possible source of criticism, although the ratings were made independently.

The standardised assessment of personality described by Mann *et al* (1981) would seem to be useful for the assessment of patients with mild and moderate mental handicap. We did not attempt to use it for individuals with severe or profound handicap and have doubts as to how well the usual personality types could be defined in this group. The method involved interviewing somebody who knew the patient well, (a trained nurse), and provided suitable data. It is very doubtful if these patients would be able to give any useful description of their own personality characteristics and an observer-based assessment procedure is therefore particularly appropriate in this population.

Many of the usual personality types were encountered although they did not always have quite the characteristic form expected in adult psychiatry. Some types did not occur at all (paranoid, anxious, asthenic) in our sample and this is in contrast with the psychiatric hospital group reported by Mann *et al* (1981). However, the explosive and hysterical types were relatively common in our hospital sample, and this may relate to the reasons for admission of these particular patients. It is not possible to draw firm conclusions about personality disorders in mentally handicapped individuals in the community from the present study.

We conclude that Mann's standardised assessment of personality questionnaire is likely to be a useful and substantially reliable instrument for rating personality in mentally handicapped patients and that it could be used in further investigations.

Acknowledgements

We are grateful to our nursing and medical colleagues for assistance and permission to study patients. Dr A. H. Mann kindly provided a copy of his questionnaire.

A Case of 'Lethal Catatonia' in a 14-year-old Girl

A case of apparent 'lethal catatonia' in a 14-year-old girl is described; similarities with earlier descriptions are identified, although the precise cause of death in this case remains somewhat obscure.

In spite of the fact that catatonia is generally regarded as having a better prognosis than other forms of schizophrenia, attention has been drawn for many years to the existence of a severe form, proceeding to death in some cases.

In 1832, Calmeil first described a stormy course in some catatonic patients, with catatonic excitement passing into profound stupor, hyperthermia, and sudden death, for which no cause was found at autopsy. In 1934 Stauder described 27 cases of fatal catatonia, half of whom were young people with a positive family history of schizophrenia, normal premorbid personalities, an acute onset, and short history of mutism, followed by 4 or 5 days of motor excitement, exhaustion, and death. He also reported skin bleeding and extreme acrocyanosis, and speculated about disorders in circulation and haemopoeisis. Subsequent reports (Billig & Freeman, 1944; Shulack, 1946; Aronson & Thompson, 1950; Laskowska *et al* 1965) also described the period of hyperpyrexia and non-specific autopsy findings. Shulack described successful treatment and recovery in nine cases where diagnosis was made early, using sedation and intravenous rehydration, with correction of electrolyte imbalance. Fish & Greiner (1960) reported a single case successfully treated by hypothermia with autonomic blockade.

Herman *et al* (1942) reviewed experimental studies on catatonia, and analysed 12 cases of catatonia in non-schizophrenic subjects. They considered that catatonia is a neurological phenomenon, the mechanism for which resides in the posterior part of the hypothalamus, with the neocortex having a controlling influence. This cortical influence was believed to be disturbed by the overwhelming toxic factors of organic cortical brain disease and also by psychological influences. In their series the catatonic symptoms were identical with those found in schizophrenia, but they suggested that the clouded sensorium of organic brain disease differentiated them.

Other writers (Weinstein *et al*, 1955; Himmelhoch *et al*, 1970; Raskin & Frank 1974) have reported cases of viral encephalitis presenting as acute schizophrenia, with unremarkable previous and family histories, and a short history of 'odd' or bizarre behaviour, sometimes proceeding to the development of catatonic stupor. They also reported the subsequent development of positive, although non-specific neurological signs and abnormal electroencephalographic recordings. Raskin, whose single case was finally diagnosed as herpes encephalitis, listed five features distinguishing between functional catatonic stupor and organic conditions: different responses of the pupils and eyelids, absence of roving eye movements in functional stupors, normal respiration, absence of abnormal motor movements such as seizures, asterixis, myoclonic movements, and the production of normal, 'schizophrenic' or depressive speech by amobarbital interview. Himmelhoch *et al* also commented on the rapid fluctuations in mental state of their eight cases and the importance of noting and correctly interpreting positive neurological signs. Most reported cases of encephalitis show pyrexia at some stage, but examination of the cerebrospinal fluid is often normal.

A single case of catatonia culminating in sudden death in a 14 year-old girl is described below; it demonstrated some of the features in the previous literature.

Case report

A. R. was admitted to a regional adolescent psychiatric unit as an emergency, at the age of 14 years 9 months, with a 9-day history of acutely disturbed behaviour. A longer history of more subtle changes emerged later.

Family background

She was the eldest of three clever daughters of professional parents. Her father was from a Jewish family, had suffered from 'idiopathic hepatitis' for some 12 years, and was also said to be cyclothymic, having received treatment for depression in the past. The mother was not Jewish and she was healthy. The only other family history of psychiatric disorder was a sister of the maternal grandfather, who was known to have spent some two years in a psychiatric hospital in her early twenties, with an illness characterised by mutism.

Past history and premorbid personality

A's birth and development was entirely normal. Her only previous illnesses were appenditicis with peritonitis at the age of 7 years and a mild episode of glandular fever at 12 years. The menarche was at 13 years, and periods had been regular, but she had tended to be overweight since then, and dieted intermittently. She had always been successful at school, had a small group of close friends, and was generally regarded by family and teachers as a mature, considerate, self-sufficient, and well-behaved girl.

History of present illness

A's behaviour had begun to change about 9 days before admission, with a series of inexplicable actions, including leaving for school half-dressed, ransacking drawers, and rowing with a neighbour. Her mood varied from elation to anger. For 6 days, she became increasingly withdrawn, with less and less speech, and an increasing tendency to rocking and other self-stimulating behaviour. She was restless, slept poorly, and ate ravenously.

On admission, physical examination was normal, except that she was overweight and her tongue a little dry. Her mental state was noted to be drowsy, passively uncooperative, rocking at times, negativistic, but with delayed response to some requests, e.g. to put out her tongue. She was perseverative with some movements, but there was no convincing waxy flexibility. She was mainly mute, but once echoed the two last words of a question. She stared vacantly, occasionally looking frightened or perplexed. It was thought most likely that the diagnosis was catatonic schizophrenia, but an organic psychosyndrome had to be excluded. The latter possibility was reinforced by her initial deterioration, which included incontinence of urine, attempting to feed herself with her hands, and several incidents of banging her legs or head hard enough to produce extensive bruising. She remained predominantly mute, but with occasional echoing or bouts of screaming. A paediatric neurologist who examined her 2 days after admission noted flexor spasms like a form of primitive seizure, and found all her reflexes to be brisk but no focal neurological signs.

Investigations and results were as follows: EEG—generalised dysrhythmia of non-specific type; CT scan—normal CSF—protein 0.6 g/litre glucose 4.0 mmol/litre, 4 RBC, 2 WBC, no bacterial growth; serum and CSF treponemal HA, cardiolipin WR and WDRL all negative; white cell and plasma enzymes—no deficiency; immunology—ANF negative; smooth muscle, mitchondria and reticulin positive; Hb 14.9 g—WBC 6.1 × 10 with normal differential, ESR 5 mm; blood chemistry—normal except alkaline phosphatase 100 *IU*/litre; LD 515 *IU*/litre, ALT 69 *IU*/litre; virus serology: evidence of past measles only; CSF antibody tests (later report) excluded any of the viruses for which tests are currently available.

For most of the 4 weeks between admission and death, she remained very disturbed, restless, sleeping only for short periods, frequently incontinent of urine and sometimes of faeces, and often removing some or most of her clothing. She frequently banged and bruised her limbs, and continued to stimulate herself sexually. Most of the time, she was mute but occasionally uttered single words or short phrases, or screamed. Her apparent mood varied from apathy to fear or elation. The facial grimacing described as *Schnauzkrampf* was noticed on several occasions, as were other mannerisms such as pointing her index finger at others. There was an interlude of an apparent brief return to normality, when she was sedated with 10 mg diazepam intravenously for the CT scan and, after awakening, for 15 min, appeared normally orientated and rational, before reverting to her former mute state.

At this stage, a presumptive diagnosis of catatonic schizophrenia was made, and treatment with chlorpromazine in increasing doses instituted; at the time of her death, she had been receiving 100 mg *t.d.s.* for one week. During the fourth week after admission, there was slight improvement with less restlessness, a better sleep pattern and more copious speech, with occasional coherence.

Four weeks after admission, she got out of bed at about midnight, having previously slept for 2 hours; as she tried to get back in, she was observed to fall to the floor. Nursing staff noticed she was cyanosed, and found her to be pulseless. Attempts to resuscitate her were continued for 40 min, during which vomit was extracted from the larynx by suction; there was no response, and death was confirmed at 1.00 am. A post mortem next day by a Home Office pathologist revealed bronchi and bronchioles full of vomit, with congestion of the lungs, a small subdural haematoma in the middle fossa, and blood on the surface of both occipital lobes. He concluded that death was due to inhalation of vomit, probably secondary to intracranial haematoma produced by repeated acts of self-injury. At a subsequent inquest, the coroner accepted the pathologist's opinion, and recorded a verdict of accidental death. Nine months later, a neuropathologist reported on further studies on the brain as follows: "the only changes that were seen were those of perivascular lymphocytic cuffing and cell changes compatible with a viral encephalitis."

Discussion

The normal family background, relatively normal family history, and rapid onset of severe symptoms and deterioration in this case seemed to indicate an organic psychosyndrome. This diagnosis was supported by the development of primitive seizures and the non-specifically dysrhythmic EEG, but not by any other investigations, including examination of the cerebrospinal fluid. The brief return to apparent normality after intravenous diazepam for the CT scan also made an organic disorder less probable. However, the eventual neuropathological suggestion of a viral encephalitis seemed an acceptable explanation of the history, clinical course, and investigation results. The cause of death seems to be a separate issue: to those immediately present her death appeared to be a very sudden one, suggesting a cardiac or overwhelming cerebrovascular cause. Staff involved in the attempts to resuscitate her found vomit in the upper respiratory passages but could not judge how long it had been there. Although the pathologist's findings adequately accounted for the death, the clinical team were unsatisfied. Neither had there been any evidence of the hyperpyrexia and extreme restlessness prior to death described by early writers. Her temperature was never appreciably raised, and if anything, she had seemed quieter and more responsive in the day or two before she died.

One feature reminiscent of Stauder's descriptions was the extensive bruising of her legs and arms. On the whole, this was thought to be consonant with her repetitive self-injury, and although it was planned to investigate for any bleeding or clotting disorder, she died before this could be done.

There remained several unanswered questions: (1) Although the later suggestion of a viral encephalitis seemed to explain most of the clinical features, is it rendered less probable by the brief return to apparent normality after intravenous diazepam? (Herman *et al* described a similar response to intravenous sodium amytal in their organic cases). (2) What was the real cause of the sudden death? (3) What might have been the longer-term psychiatric outcome, had she lived?

Acknowledgements

I am very grateful to Dr Elena Garralda for translating Stauder's paper from the German, and to my secretary, Mrs K. Critchley.

Cotard's Syndrome in a Mentally Handicapped Man

A mentally handicapped man with Cotard's syndrome is described, and the usefulness of electroconvulsive therapy in his management discussed. Even the more uncommon psychiatric syndromes such as this can be found in people with lower intellectual functioning, with clinical features little modified.

Delire de negation was first described by Cotard in 1880, in a presentation to the Société Medico-psychologique in Paris and his name was given to the syndrome by Seglas (1897). Its chief characteristic is a denial by the afflicted person of his own existence, that of part of his body, or in extreme cases, his whole environment. It has long been debated whether this is a clinical entity in its own right, or a complex of symptoms which may be associated with any of a number of psychiatric illnesses, most notably depression. A comprehensive review of the literature has been given by Enoch & Trethowan (1979).

Although there has been an increased interest of late in psychiatric illnesses in the mentally handicapped, with some accounts of unusual syndromes, e.g. Gilles de la Tourette syndrome (Burd & Kerbeshian, 1985; Reid, 1984), there has been no description of the phenomenon of Cotard's syndrome in a mentally handicapped person. I here describe such a case.

Case report

The patient is a 67-year-old man who has been resident in a large hospital for the mentally handicapped for the last 27 years; he was admitted after the death of his mother, as it was felt that he could not manage to live an independent existence. At admission, his IQ was assessed as 35. Although he has always been well settled in hospital, he has, for almost his entire time there, been prone to bouts of depression, frequently accompanied by bizarre ideas. During his first recorded episode, he stated that he had "no head" and "eyes only sometimes"; on another occasion, he said that the floor was "soft". His personality was described as hypochondriacal, with a tendency to complain about minor ailments.

His most recent episode began when he was observed by nursing staff to be "confused". After an initial apparent recovery, he once again began to deteriorate, lost interest in his hospital activities, and took to bed, complaining of abdominal pain; when asked why he would not get up, he could not elaborate, and answered "I don't know" to most questions. He began to refuse food, and told nurses that he had no body, no legs, and should be in the hospital mortuary. At this stage, because of enfeeblement due to his poor dietary intake, he was transferred to the sick ward. He continued to express nihilistic ideas, stating that his bowels were missing, and to refuse food and fluids; when asked why he was doing this, he said that he was dead, and that, as he was dead, he should be in the hospital mortuary "where all the dead people go". Asked "What would you do there?", he replied "Go into the fridge". At about this time, it was discovered from discussions with ward staff that a friend of his—a man in another ward—had recently died.

Despite two courses of antidepressants, there was no significant improvement in his condition. (Mianserin was initially administered, up to a maximum dose of 30 mg mane and 60 mg nocte. As this was ineffective, it was replaced after 7 weeks by nomifensine 25 mg *t.d.s.*) It was therefore decided, because of his declining physical health, to commence a course of electroconvulsive therapy (ECT) which, on a previous occasion, had proved effective in resolving a similar episode. Nomefensine was continued during and after ECT. Six treatments were given. The response was slow, but positive; he continued to express delusions, and on a few occasions, was found near the mortuary, again voicing ideas that he was dead and should be in there. At the end of the course, he was eating again, but was still quite taciturn and withdrawn. He then gradually returned to his premorbid state—began talking to staff and other residents, and participating in hospital activities. At this point, he returned to his own ward where he continued to make gains, and in fact became slightly elated for a short period, with mild disinhibition and expansive good humour.

Discussion

The development of a firmly held delusional belief, clearly expressed, in a mentally handicapped man with limited powers of communication, is a phenomenon worthy of note in itself, and the manner of its development bears consideration: an initial stage of poor concentration and apathy was followed by the gradual decay in his sense of personal integrity. His concern with abdominal pain characterised the early phase; giving way to a more profound disintegration, with first a denial of parts of his body and finally a conviction of his own death, which was of sufficient strength and coherence for him to act on it, and ask to be treated as dead. Interwoven with these symptoms were those of a depressive illness, with withdrawal, anorexia, depressed mood, and weight loss.

The aetiology of his illness may be seen in a number of ways. It is well recognised that, in the more severely mentally handicapped, an organic component is likely to be important in the production of the handicap, and Cotard's syndrome has also been associated with organic brain abnormality (Anderson, 1964). An association with hypochondriasis in Cotard's syndrome was also recorded by Anderson (1964). This patient had been described as being of a hypochondriacal personality, but the possibility that his symptomatology was related to a grief reaction is also a strong one. On the two occasions of his most severe episodes of nihilistic delusions, there had been a recent death of a close friend in the hospital. It seems very probable that his premorbid personality structure, his recent experience of death at close quarters, and a more concrete comprehension of events due to his intellectual handicap predisposed him to decompensate in the manner in which he did.

Antidepressants of various types proved ineffective in his earlier management, in spite of their having been tried in adequate doses over appropriate lengths of time. However, ECT produced a more satisfactory response, with an eventual full resolution of his pathological symptoms; it was also noted that there appeared to be a response to the use of minor tranquillisers, in the form of short-acting benzodiazepines, which seemed to bring about a reduction in his agitation, with an associated improvement in mood. The usefulness of ECT in the syndrome was recorded by Enoch & Trethowan (1979), and it is of interest that its effectiveness in a mentally handicapped subject was similar to that in normal subjects.

This case demonstrates once more that it is possible to find presentations of even the more uncommon psychiatric syndromes in mentally handicapped people, with features little modified by their lower intellectual functioning. It also underlines the fact that just as the symptoms can be of a relatively conventional nature, so also can be the treatment: ECT was as useful in this case as it has been in people of normal intelligence.

Senile Dementia and Parietal Lobe Dysfunction

Two samples of patients suffering from senile dementia were administered the Kew tests for parietal lobe function and aphasia. No evidence emerged of any clinical heterogeneity; parietal lobe test performance was found to be more a function of degree of impairment rather than of age.

Interest in the clinical differentiation of patients with senile dementia has a long history. Several earlier writers had suggested a distinction between 'simple' or benign senile dementia, and a more clinically impaired or symptomatic type (cf. Bleuler, 1928, Schenk, 1955). As growing evidence emerged of similar underlying neuropathology in presenile Alzheimer's disease and senile dementias, however, a clinical unity has been drawn (cf. Rossor, 1982). Nevertheless, interest has been maintained in possible heterogeneity in both clinical manifestations, aetiology and prognosis within the primary degenerative dementias of Alzheimer type, especially with regard to differences in age and focal cortical signs (cf. Seltzer, 1984).

A much quoted study was reported by McDonald (1969) who distinguished between type A and type B senile dementia patients, on the basis of signs of parietal lobe dysfunction. Type A referred to patients making more than one error on a six-item 'parietal' scale, whom McDonald found to be younger and yet to have a significantly enhanced mortality. In a later paper, Hare (1978) claimed that using McDonald's measures, patients who showed only memory impairment and disorientation but no parietal signs had quite favourable outcomes, unlike the clear dementias who had poor outcomes (and parietal signs). Roth (1980) has argued, however, that "focal features . . . after the age of 70 can rarely be given the same status as the parietal lobe phenomena found . . . in the fifth and sixth decades".

While not employing McDonald's measures, other studies have examined different clinical features in senile dementia in relation to subsequent mortality, and two studies have demonstrated a relationship between 'temporoparietal' signs and enhanced mortality (Kaszniak *et al*, 1978; Naguib & Levy, 1982). At the same time such parietal lobe features as drawing ability and such temporal lobe features as nominal aphasia have been shown to correlate strongly with measures of severity of cognitive impairment within a population of senile dementia patients, supporting Roth's comment that focal features do not represent unique clinical phenomena in these cases, and thus may not be useful bases for a meaningful source of clinical heterogeneity (Skelton-Robinson & Jones, 1984; Moore & Wyke, 1984).

In neither McDonald's nor Hare's papers are there signs to exclude deliberately cases whose clinical features may have suggested a vascular aetiology to the dementia. In attempts to replicate McDonald's findings it would seem necessary (as he recognised at the time) to try and exclude possible cases of vascular (multi-infarct) dementia, and indeed to minimise the effects of physical health and of long-term institutionalisation. The present report describes data from two studies employing McDonald's Kew test, on patients selected to avoid the above complicating factors.

Method

Subjects

The first group of patients were seen and tested by E. S. using the Kew Cognitive Map. They were 20 female patients aged 65 or over attending psychogeriatric day hospitals or recently admitted to a psychogeriatric unit. All had a clinical diagnosis of senile dementia, no psychiatric history before the age of 65 years and none of the usual indices of possible multi-infarct dementia (i.e. no history of stroke, no focal neurological signs, no history of hypertension, no peripheral atherosclerosis). Laboratory investigations had not revealed any evidence of associated physical disorders. Mean age of this sample was 80.1 ± 4.6 years (range 70–87 years).

The second group of patients were seen and tested by R.O'C. using the parietal and aphasia scales of the Kew Map. Eighteen patients were selected on the basis of being in good health, attending a psychogeriatric day hospital while living at home, having a clinical diagnosis of senile dementia, no previous psychiatric history, age over 65 years, and a Hachinski index of 4 or less (Hachinski *et al*, 1975). Mean age of this sample was 78.3 ± 5.5 years (range 66–86 years).

All the patients had at least a 6-month history of mental deterioration and forgetfulness, all could repeat at least three digits forward, and all were capable of some degree of self-care. It is very difficult to date accurately the onset of dementia; however, no subjects with obvious presenile dementia were included in the analysis.

Measures

Both groups were tested on the 'aphasia' and 'parietal' subscales of the Kew Cognitive Map (McDonald, 1969). The Kew Aphasia test requires the subject to (1) name a wristwatch, (2) name the wrist strap or band, (3) name the buckle or clasp, and to state what the following appliances are used for: (4) refrigerator, (5) thermometer, (6) barometer. The Kew Parietal test was not described in detail by McDonald (1969). The version used in the present study required the subject to (1) show left hand on request, (2) touch left ear with right hand, (3) identify an object (key or coin) by touch alone, (4) correctly identify finger or hand when touched, (5) demonstrate normal 2 point discrimination, (6) construct a square with matches.

In both groups, apart from the Kew parietal and aphasia scales, the patients also completed other psychological tests, including a mental status test. The first group completed a 10-item extension of the Kew 'memory scale', the second the 12-item Information/Orientation scale of the C.A.P.E. (Pattie & Gilleard, 1979). Given the equivalence of most mental status test measures, the differences in these two tests seemed unlikely to be of significance (cf. Gurland, 1980).

Results

Table I presents the cross-tabulation of the aphasia and parietal scales. The rank order correlation between the two scales is +0.70, $P<0.001$, indicating a significant association between 'temporal lobe' and 'parietal lobe' signs. However, while patients who do badly on the aphasia test may still make no errors on the parietal test, the reverse is not the case, suggesting either that the appearance of 'parietal' signs is a later, more severe index of deterioration or that the test items in the aphasia scale are simply more difficult to perform.

When the sample is split according to McDonald's 'A' and 'B' types (A = those scoring more than 1 error on the parietal scale, B = those scoring 1 or less), and their mean

TABLE I

Cross-tabulation of Kew Aphasia and Parietal Scale Scores

Kew Parietal Scale	*0–1*	*2–3*	*4–5*	*6*	*Total*
Kew Aphasia Scale					
0–1	2	1	3	1	7
2–3	0	2	9	2	13
4–5	0	1	2	11	14
6	0	0	0	4	4
Total	2	4	14	18	38

ages compared, no differences emerged. Group A X age = 79.0 years, $n = 13$; group B X age = 79.3 years, $n = 25$. In the first group of patients the correlation between age and parietal score was $\rho = -0.077$ and in the second group $\rho = 0.085$, both non-significant. Rank order correlations between the two samples' mental status test scores and aphasia scores were: $\rho = +0.63$ ($n = 18$) and $+0.59$ ($n = 20$); between mental status test scores and parietal scores: $\rho = +0.59$ ($n = 18$) and $+0.16$ ($n = 20$). The latter correlation is not significant: all others are significant at $P < 0.01$.

Discussion

The findings do not support McDonald's qualitative distinction between a younger parietal lobe-impairment group and an older benign parietal lobe-intact group of patients diagnosed as senile dementia. Rather the study suggests a general relationship between existing deterioration in mental status and the accumulation of 'cortical' deficits. (The insignificant correlation between mental status test score and parietal score in Group 1 is an exception.) Since 'parietal' signs seem to occur later than 'temporal lobe' signs, it might be expected that their presence will augur an increased probability of dying in the near future. Of course this assumed 'sequence' of deterioration may reflect the different level of difficulty of the items in the 'parietal' and 'aphasia' tests rather than the true progression of dementia. However, recent evidence (Colgan, 1985) seems to confirm that level of mental deterioration reflected in impaired mental status performance is of equal if not greater prognostic significance than 'parieto-temporal' impairment scores in predicting mortality within a dementing population.

The age differences that were observed in McDonald's study may be explicable when those factors leading elderly patients to be admitted into long-term care are considered. Thus Green & Timbury (1979) have reported that their day hospital patients who were married and subsequently institutionalised were behaviourally more deteriorated than similar patients living alone. Since older patients, especially older women, are more likely to be living alone, this may lead to their being less deteriorated on admission—findings which have indeed been noted from behaviour ratings (Gilleard, 1978).

It is possible that, as Roth (1980) suggests, in presenile dementia such cortical localising signs may be significantly more frequent and distinctive compared with senile dementia patients. Nevertheless, empirical studies such as those reported by Pearce & Pearce (1979) have not reported any greater frequency of 'dysphasia, dyspraxia or agnosia' between pre-senile and senile groups. Similar conclusions to those indicated here of a global progression in the development of cognitive deficits in dementia have been reached by Reisberg and his team (Reisberg, 1984). The weight of empirical evidence does not at present provide much support for any clear-cut clinical heterogeneity in the primary (non-vascular) dementias.

Finally, it may be argued that the failure to replicate McDonald's findings reflects the inadequacies of the Kew Cognitive Map, rather than the unimportance of parietal lobe dysfunction in differentiating subtypes of senile dementia (witness the evidence from CT regional density studies, such as those reported by Colgan, 1985). Whilst this may be so, the burden of proof remains for investigators to show that clinical signs of parietal lobe impairment do indeed contribute unique information concerning the course and nature of senile dementia, rather than merely reflecting the severity of deterioration.

Brain Imaging in a Case of Capgras' Syndrome

A patient developed Capgras' syndrome as part of an interictal psychosis of epilepsy; magnetic resonance imaging revealed bilateral subcortical lesions in occipitotemporal and frontal regions. These findings have implications for the postulated association between Capgras' syndrome and neuropsychological deficits, in particular prosopagnosia.

The delusional misidentification of closely familiar persons as being alien imposters, despite the acknowledgement of an extreme resemblance, is known as Capgras' syndrome. This phenomena has attracted a variety of explanations. Capgras & Carette (1924) offered a psychoanalytical interpretation of the second case described, and such explanations still have their adherents (Berson, 1983). However, in their original description, Capgras & Reboul-Lachaux (1923) noted a prodrome of derealisation, and suggested that it was this compelling feeling of strangeness which determined the emergence of the delusion—a view which has found support in similar observations by Christoloudou (1977) and by Todd *et al* (1981). Others have remarked on the frequency of organic brain disease, and have proposed that underlying neuropsychological deficits, such as prosopagnosia (Hayman & Abrams, 1977) or sensory inattention (Stuss & Benson, 1984) are important in its evolution. These concepts are appealing, but remain speculative. The new brain imaging techniques, however, offer an opportunity to test such hypotheses in a more direct way. A case of Capgras' syndrome is described, in association with unusual cerebral lesions whose relevance to observed neuropsychological impairments and to the syndrome itself are of interest.

Case report

Jane is a 19-year-old, left-handed girl, the youngest of five daughters of caring, professional parents. There is no family history of psychiatric disorder or epilepsy. She was born by difficult forceps delivery, 2 weeks post-mature, and it was thought she had suffered perinatal intraventricular haemorrhage, although lumbar punctures were repeatedly negative. After being nursed in an incubator for 8 days, she recovered well, and milestones were within normal limits. At the age of 5 years, she developed complex partial epilepsy: her seizures comprised absence attacks, lasting several minutes, during which she would be unresponsive, clench her fingers, and pluck at her clothes. She often experienced a brief prodrome of flashing coloured lights.

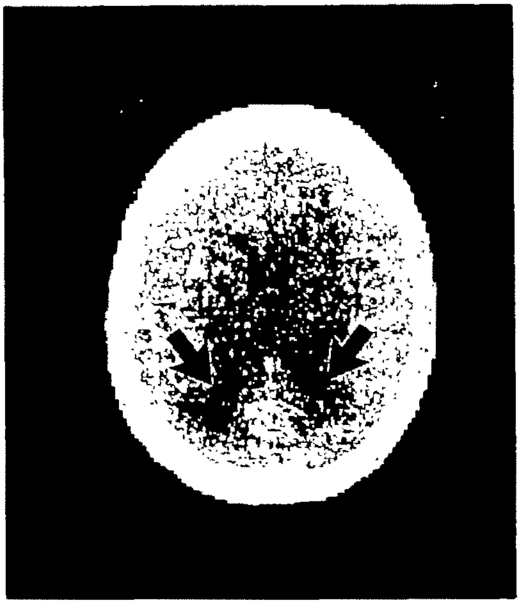

FIG. 1. Computerised tomographic scan showing bilateral occipitotemporal lesions (arrowed).

She had a single convulsive fit at the age of ten and her seizures continued without remission, on an almost daily basis, despite treatment with several different anticonvulsant drugs. Annually repeated EEGs consistently showed bilateral occipitotemporal slow waves, more prominent on the right. Observed seizures were accompanied by high amplitude spike activity in the left posterior temporal area.

As a child, Jane showed problems in discriminating the identities of her familiars; she would often hold the hands of other women, when out shopping with her mother. Psychometric assessment at the age of 18 revealed a verbal IQ of 72, a performance of 61; word-finding difficulties were evident and on tests of learning and memory she was globally weak. She was apraxic, but her most severe deficits were noted to be in visual perceptual processing. Here, although basic shape perception was intact, she showed difficulties in more complex aspects of visual processing, which were most marked on tests of memory for faces and designs. Nonetheless, her social skills were well developed, and she was verbally expressive. Computerised tomography (CT) at this time revealed bilateral occipitotemporal areas of low density, likely to represent infarction (Fig. 1). Neurological examination was normal, apart from a left divergent squint, slight impairment of colour vision, and isolated small scotomata in the absence of gross field defect.

She showed no psychiatric or behavioural symptoms before her admission at the age of 19 to a specialist residential unit for epilepsy; she was then taking carbamazepine and phenytoin, with therapeutic plasma levels. Shortly after her admission, an increased dose of phenytoin was prescribed inadvertently: after 7 days at this higher dosage, her daily fits ceased. Over the next 3 days, she

became agitated, and described third-person auditory hallucinations of family members, with the secondary delusion that God had suddenly equipped her with supersensitive hearing. She was fully orientated in time and place. Plasma phenytoin at this time was almost twice the upper limit of the therapeutic range. Despite prompt withdrawal of the phenytoin, her psychotic symptoms persisted, and she experienced fleeting complex visual hallucinations, on one occasion seeing the decapitated corpse of her boyfriend. She became suspicious of the staff, and her mood was labile. When her family visited, she failed to recognise her sister, who had a new hairstyle, claiming instead she was a long-dead maternal aunt. The following day, she was convinced that her mother, father, and sisters had been replaced by "dummies", who visited with the intention of kidnapping her; she believed that these imposters lived at an identical house nearby, and also owned a replica of her pet cat. She said that they held her real family as prisoners, and were torturing them. When questioned, she stated that whereas the "dummies" looked exactly like her real family, they possibly dressed differently, and that her mother had given her a tighter hug than usual. This delusion lasted about a week, after which her fits returned at their previous frequency. Magnetic resonance (MR) imaging confirmed the presence of the bilateral occipitotemporal lesions, and also revealed smaller symmetrical lesions in the frontal region (Fig. 2). The appearance and distribution of these lesions suggested them to be old infarctions at the 'watershed' areas between the middle and posterior, and middle and anterior, cerebral arteries respectively. The lesions were not seen to extend to the cerebral cortex.

At 6-month follow-up, she reported experiencing occasional auditory pseudo-hallucinations, but had full insight into her past psychopathology. The diagnosis was of a schizophreniform psychosis, arising as an interictal psychosis of epilepsy, apparently precipitated by phenytoin overdosage. Both the form and content of the psychosis were presumably influenced by the nature and situation of pre-existing cerebral lesions.

Discussion

This case illustrates well the organic epiphenomena often reported in patients with Capgras' Syndrome. Evidence of pre-existing cerebral disease—in this case temporal lobe epilepsy—is commonly found (Cummings, 1985). Electroencephalographic abnormalities are frequently seen, and usually take the form of paroxysmal bitemporal slow wave activity, as here; in some instances, the EEG changed as the psychosis resolved (MacCallum, 1973). Neuropsychological impairments have attracted much attention. Christoloudou (1977) found specific impairments of visuospatial perception and memory in nine out of ten patients tested systematically; these findings have been taken as further circumstantial evidence for a regional deficit in Capgras' syndrome, more specifically in the non-dominant occipitoparietal area, although not all patients tested have shown this pattern. Some perform normally (Merrin & Silberfarb, 1976), or show evidence of frontotemporal impairment (Morrison & Tarter, 1984). Classical prosopagnosia, in the sense of an isolated loss of the ability to recognise previously familiar faces, has never been satisfactorily demonstrated in patients with Capgras' syndrome. However, difficulties in facial recognition—as part of a more general impairment in higher visuospatial function—have been recorded in several patients, and were again observed in the case described here.

Results of CT have been reported in four cases of Capgras' syndrome: appearances were normal in one patient (Thompson *et al*, 1980), while changes suggestive of cortical atrophy were seen in two (Todd *et al*, 1981; Quinn, 1981). In the fourth case, Alexander *et al* (1979) reported marked frontal and right temporal atrophy in a patient who developed Capgras' syndrome following a severe head injury; on this basis, it was suggested that frontal lobe impairment was important in the genesis of the syndrome. However, this patient also showed visuospatial deficits on testing, and his psychopathology was atypical, in that he showed a jovial, apathetic affect in place of the suspiciousness regarded by many as characteristic of Capgras' syndrome (Todd *et al*, 1981).

MR imaging is superior to CT in identifying areas of cerebral infarction, particularly where these lie close to the bone (Bydder, 1983). In the patient described above, roughly symmetrical bilateral lesions were revealed in the occipitotemporal and, to a lesser extent, frontal regions. Previous CT showed that these lesions were present before the onset of Capgras' syndrome, and the clinical history implies that they were lifelong. The possible role of perinatal cerebrovascular damage in some psychoses has been discussed recently (Murray *et al*, 1985). In the light of these findings, can anything further be said about the relationship between neuropsychological deficits, in particular prosopagnosia, and Capgras' syndrome?

Like Capgras' syndrome, prosopagnosia (Bodamer, 1947) is a rare disorder, whose aetiology has provoked much speculation; it is usually accompanied by a visual field defect and a disturbance of colour vision. A primary face-specific perceptual impairment has been the mechanism favoured in the past (Whiteley & Warrington, 1977), and this was thought to reflect damage to the non-dominant occipitoparietal cortex, but more recently, this interpretation has been questioned. Studies with split-brain subjects have demonstrated that both hemispheres are capable of facial recognition, although different strategies may be employed (Levy *et al*, 1972). Prosopagnosic patients recognise and can name the component parts of a face, as well as knowing that what they observe is a face. Indeed, unfamiliar faces can often (but not always) be discriminated well, while accurate perception of other highly complex visual stimuli is possible. What suffers is the recognition of previously familiar faces and, occasionally, other visually similar, once-familiar items: Damasio (1985) cites a prosopagnosic farmer no longer able to recognise individual animals previously well known to him. These observations have led to the alternative hypothesis that the primary defect in prosopagnosia is not of perception but of memory—the perception is correct, but it fails to elicit the appropriate associated contextual memories which usually provide the experience of familiarity. These memories can still be triggered by non-visual stimuli so that a person's voice will prompt recognition, but not his face. Furthermore, instead of showing a non-dominant occipitoparietal lesion, almost all patients with prosopagnosia who have come to post mortem (Meadows, 1974) or computerised tomography or magnetic resonance imaging (Damasio, 1985) have shown bilateral occipitotemporal lesions, highly reminiscent of those found in the patient reported here. Patients with similarly placed unilateral lesions, or bilateral occipitoparietal lesions, do not show prosopagnosia (Damasio *et al*, 1982). The bilateral lesions are functionally symmetrical, and involve the subcortical pathways by which complex visual information is passed forward to the temporal lobe. From this, a disconnection of limbic structures from the visual association cortex has been proposed as the mechanism responsible for prosopagnosia (Damasio, 1985). Could a similar mechanism be operating in Capgras' syndrome?

The idea of a possible relationship between the disorders has been rejected for several reasons. Firstly, they have not been shown to co-exist: patients with prosopagnosia do not show psychiatric symptoms and, conversely, classical, isolated prosopagnosia is not displayed in Capgras' syndrome. However, it is clear that many patients with Capgras' syndrome do show a more generalised visuospatial impairment, of which poor facial recognition is an important part. Secondly, the restriction of Capgras' syndrome to the identity of those most closely familiar to the patients is an observation often used to discount organic explanations in favour of psychodynamic ones (Berson, 1983), yet prosopagnosia shows exactly the same pattern. The third objection is that the natural history of the two disorders differs, the assumption being that Capgras' syndrome is essentially episodic, whereas prosopagnosia is a permanent neuropsychological deficit. Again, this is not necessarily true: Capgras' syndrome may be remarkably chronic, and reports of episodic prosopagnosia exist. Whiteley & Warrington (1977) cite a case of prosopagnosia which resolved during radiotherapy to an occipital tumour and, more pertinent to the present case report, Agnetti *et al* (1978) described a patient with recurrent, short-lived prosopagnosia which proved to be an ictal phenomenon. Lastly, critics point to the lack of an established neuropathology common to the two conditions. This is challenged by the findings of the present report; the detection of such lesions obviously depends to some extent on the sensitivity of the instrument used.

That organic factors operate in Capgras' syndrome is increasingly evident and the demonstration, in such a patient, of lesions apparently characteristic of prosopagnosia strengthens the conceptual link between the two disorders. They remain separate clinically, but in at least some cases of Capgras' syndrome, a neuropsychological mechanism analogous to that postulated for prosopagnosia might be at work. Thus, by reason of a functional disconnection between the central visual system and the temporolimbic lobe, a correct perception fails to evoke the normal affective memories tied to it. The result might best be regarded neither as an illusion (Cutting, 1985), nor a delusion (Berson, 1983), but as a confabulation.

Alcohol-related Psychiatric Emergencies: Their Characteristics and Care at a Walk-in Clinic

Fifty cases attending a walk-in psychiatric emergency clinic with alcohol-related problems were studied retrospectively. Results confirm that this group represents a sizeable load on the clinic – about 15% of all assessments. Other psychiatric problems were common, and many patients had recently attempted or threatened suicide.

Alcoholism and alcohol-related problems have long been regarded as a substantial demand on emergency services. In the USA, Rund *et al* (1981) estimated the overall prevalence of alcoholism in patients attending a general emergency department as high as 20%. In the UK, a study of casualty attenders found that of those who presented with psychiatric disorder (2.2%), 10% were for alcoholism (Anstee, 1972). In a psychiatric emergency clinic, Jones (1979) discovered a serious rate of missed diagnoses of alcoholism amongst patients subsequently admitted, though Lim (1983), examining the same clinic, still found 10% of index cases to have a diagnosis of alcoholism or drug dependence.

Clinical practice suggested that there were higher rates of alcohol-related disorder, and in the absence of other relevant work, it was thought appropriate to examine in detail the size and nature of the problem. It was hoped that these data would provide useful information to those intending to improve or design alternative services. The study is based on the Maudsley Hospital Emergency Clinic, which has been well described in other work (Brothwood, 1965; Mindham *et al*, 1973; Lim, 1983). The Bethlem Royal and the Maudsley Hospitals are referred to as the Joint Hospital.

Method

To minimise seasonal bias, cases were collected from two separate 2-week periods, 6 months apart: the middle two weeks of November 1981 and the corresponding weeks in May 1982. Clinic's journal; all such cases were found to have major alcohol problems.

Using a coded schedule, data were abstracted retrospectively from the case notes. Information was coded by two raters: a nursing sister from the Alcohol Treatment Service and the author. The study of Edwards *et al* (1976) indicated that inter-rater reliability could be a cause of concern in abstracting data from case notes with this group of patients, but preliminary checks confirmed that both inter-rater reliability and the standard of case note recording was generally high.

Results

Size of the problem

Over the 4-week study period, 50 patients with alcohol-related problems were identified: this amounted to 66 separate presentations, out of a total of 447. Thus, 14.9% of the emergency clinic assessments had alcohol-related problems.

Social characteristics

The mean age of the sample was 41.9 years, with a range from 23 to 75 years. The sex distribution revealed 33 males and 17 females. 19 were currently married or had been co-habitating with a partner for 6 months or more, and only four were listed as having no next of kin. Social class as defined by the Hall-Jones Scale of Occupations Prestige (Oppenheim, 1966), based on best-ever reported occupation, showed a span between class 1 and class 8. The employment rate was low, with only ten being currently in work. The majority of patients (66%) came from outside the Hospitals' catchment area; seven were recorded as having no fixed abode.

Past treatment histories

Only 15 were classified as new patients to the Joint Hospital; 21 were current attenders (had attended sometime within the last 6 months), while the remaining 14 were categorised as new-old patients. Therefore, over two-thirds of these patients had had previous treatment at the Joint Hospital. However, only a third of these (11) had attended the Alcohol Treatment Service, and only five of them were current attenders. A substantial number of those registered as patients of the Joint Hospital were (or had been) receiving help for their alcohol problems in other departments: 11 as past outpatients, eight as past inpatients, and four currently attending an outpatient clinic.

A history of past treatment of alcohol-related problems outside the Joint Hospital was another common feature. At other hospitals, 19 had been inpatients, 14 past outpatients and one a current outpatient. Six had been through a community-based detoxification unit. Eight at some time had stayed at a rehabilitation hostel, and one was currently resident in such a hostel.

Source of referral

Self-referral was the most common means of introduction to the clinic, accounting for 21 cases. Other sources included: general practitioners (28%), other hospitals (16%), community agencies (4%), and the police (2%). Interestingly, none came from those agencies specifically helping alcoholics. All patients attended on a voluntary basis, none being brought or detained under the Mental Health Act.

Presenting problems

Drinking problems

Just over a quarter (14) requested help for symptoms of alcohol withdrawal. In all, eight asked for medication to stop or reduce their alcohol consumption, while only one case was noted to want help because of a physical problem—alcohol-induced gastritis. Over half (29) cited other problems e.g. an inability to cope leading to demands for admission, general distress and depression associated with alcohol, drinking causing marital problems, black-outs, and a case of alcoholic hallucinosis.

Other psychiatric problems

Nearly half (23) complained of feeling depressed, but only eight were noted to have anxiety. Other symptoms were recorded in 14 cases and included auditory hallucinations in three patients, distress over their persistent antisocial and aggressive behaviour in two, cognitive deficits in two, visual illusions in two; and in single cases, persecutory delusions, hypomanic mood swings, premature ejaculation, and dysmorphophobia.

Social problems

Nearly 90% had evidence of social problems and, for many, in several areas of their life. The most frequently reported were marital difficulties—in 15—i.e. three-quarters of those married. Other common social problems lay in the areas of family relationships (in 24% of all cases), accommodation (22%), difficulties at work (18%), and other relationship problems (18%). Surprisingly, recreational difficulties were recorded in only one case.

Associated deliberate self-harm

Nearly a quarter had committed, within a week of presentation, an act of deliberate self-harm which was noted to relate to their current difficulties: ten cases had taken a tablet overdose and another two had cut their wrists.

Behaviour at attendance

Levels of intoxication from alcohol were categorised as follows: six cases were documented as drunk, intoxicated or ataxic; five as 'smelling of alcohol'; and in nine others, although there was no evidence in the clinical notes, they were recorded as 'alcohol overdoses'. The single case who was described as unco-operative and six more who refused to co-operate with history taking were all in this intoxicated group.

Threatening behaviour to others was noted in five cases: three issued only verbal threats; one was both verbally and physically threatening, and one threatened physical violence by waving a knife about. In this last case, the man was suffering from symptoms of acute alcohol withdrawal, but in the others, two males and two females, there was evidence of ebriation. Three patients caused minor damage to hospital property. Threats of self-harm were more common, being noted in 14 cases: the majority of these (nine) had already made a deliberate attempt to harm themselves, but five had not.

Diagnostic practices

Duty doctors commonly listed two diagnoses, and occasionally three. In descending order of frequency, these were in the following broad categories: alcohol-related disorders, depression, personality disorder, and stress reactions. There were no diagnoses of schizophrenia.

Treatment given

Just over half, 28, received a prescription; the use of medication was unremarkable. Only in 17 cases was there evidence that any advice had been given to patients; this covered: abstaining from drinking, going to a voluntary agency, registering with a GP, or returning when sober. Three referrals were made to Alcholics Anonymous, and in one of these it was not the patient but his family who were advised to go.

Discussion

Virtually 15% of patients assessed at the Emergency Clinic were found to have alcohol-related problems; this indicates the substantial size of the problem, and, moreover, it is likely to be an underestimate. Duty doctors may not recognise all cases of alcohol dependence (Jones, 1979), and other patients may have escaped inclusion through a failure to record their alcohol misuse.

Patients with these problems showed a broad range of social characteristics, with one exception; there were none younger than 23 years, so that it is likely that young persons who are abusing drink are not seeking help at the Clinic. Although the great majority had a recorded next of kin, this may belie the true rate of social isolation, as the study could not appraise how many had actually become alienated from their stated relatives and friends.

Despite the 'emergency' nature of the Clinic, only in one in six could it be stated that they had not received previous help for their drinking problems. Indeed, the impression given is that this is a group of patients suffering from chronic distress, repeatedly presenting at times of crises to any available source of help. The high frequency of previous treatment attempts only highlights the importance of providing long-term therapeutic support.

Psychiatric complaints, suicidal behaviour, and complications of alcohol withdrawal make it mandatory for appropriately skilled doctors to be involved, but the large number of social problems suggests an advantage in also involving other professionals. Busy duty doctors covering the Clinic tend to give precedence to cases with more obvious mental illness; the social aspects of distress may be no less deserving of attention, but could be dealt with by others. The finding of only one recording of recreational difficulties commonly associated with alcohol misuse, suggests that relevant social problems are being neglected.

Alcohol intoxication was associated with many of the problems encountered in psychiatric assessment. Of the minority who showed threatening behaviour or could be regarded as unco-operative, all but one—who was suffering from acute withdrawal—was inebriated. However, from the very nature of this population, it would have been expected that many would have consumed alcohol, but in those who proved troublesome, documenting a state of intoxication might have been considered particularly important as a possible explanation. Such a tendency could serve to exaggerate the connection between intoxication and difficult behaviour.

Curiously, there was an absence of schizophrenia from the diagnoses. This could be due to the small sample size, but is perhaps more likely a result of diagnostic bias at initial assessment, when symptoms of psychotic illness might foreshadow abuse of alcohol.

Whereas little criticism could be made of the Clinic's prescribing habits, this cannot be said about other therapeutic options: only in a third of cases was there written evidence that advice had been given, though it is possible that advice was more often given but not recorded. Indeed, when there is an awareness of the importance of a therapeutic strategy, not only is it more likely to be performed, but its execution will also be documented. Therefore, it must be assumed that deliberate use of 'strong medical advice' to stop, with a warning of the outcome of continued drinking, was largely an absent therapeutic force. In addition, there was very little use made of community agencies helping alcoholics; though the potential value of community-based detoxification services, counselling agencies, and Alcoholics Anonymous can be enormous, these resources went virtually untapped. This lack of interaction seems to be mutual, as there were no referrals to the Clinic from these agencies. Better training of staff from all centres would engender a more active awareness of local facilities, and would also be useful in directing this mostly unemployed group towards potentially rewarding occupational and leisure opportunities.

It has been argued that these patients still require psychiatric assessment, but in view of the limitations on medical time, counselling and referral to community facilities could be undertaken by others. As nursing staff already man these units around the clock, suitable candidates could receive the necessary training to enable them to fulfil this role. The work could be incorporated along with other duties, and should therefore not require any substantial increase in manpower. Furthermore, having nurse counsellors on the regular clinic staff should also promote better liaison with community facilities, which in turn might improve the effectiveness of aftercare, and lead to a decrease in the numbers presenting in crisis. It is difficult to demonstrate the efficacy of providing such an extra service, but this is a group of patients who demand help, are severely distressed by their predicament, and tend to cause concern to family, friends, and all those involved in their welfare. It is a need which surely calls for further therapeutic endeavour.

Genetic Markers in Late Paraphrenia: A Study of HLA Antigens

Patients with late paraphrenia were typed for HLA-A, -B and -C. Increased frequencies of BW55 ($P=0.036$), B37 ($P=0.008$) and CW6 ($P=0.056$) were found relative to controls. Unlike findings in paranoid schizophrenia, there was no HLA-A9 association, suggesting that paraphrenics may be genetically distinct from schizophrenics. The primary association seems to be with B37, which has the lowest corrected P value and highest relative risk; if this were replicated, it would make possession of this antigen a strong risk factor for developing the disorder.

Most studies of paraphrenia have concerned themselves with descriptive aspects, so that very little is known about possible aetiological factors. Why does a 'normal' individual become overtly psychotic for the first time late in life? Abnormal personality of paranoid or schizoid type, prolonged social isolation, and long-standing sensory defects—deafness and/or visual impairment—have all been implicated in the genesis of late paraphrenia. (Kay & Roth, 1961; Post, 1966; Herbert & Jacobson, 1967; Cooper *et al*, 1974).

The genetic contribution to paraphrenia (or rather, to the liability to develop the disorder) is still undetermined. Various studies have estimated the risk of developing schizophrenia among relatives of probands with late-onset schizophrenia and of patients with more chronic forms of the illness; the general conclusion has been that relatives of late-onset patients have an appreciably lower risk of developing schizophrenic disorders (Funding, 1961; Kay, 1963, 1972). Although this might be interpreted as showing that the two conditions are distinct, the findings are also consistent with the notion of a multifactorial genetic-environmental continuum of liability (Reich *et al*, 1972), with the disorders differing quantitatively, but not qualitatively, with respect to genetic loading, Farmer *et al* (1984). Another obvious demographic difference is that late paraphrenia shows a female predominance, while schizophrenia affects both sexes equally, but the age of onset of schizophrenia in females is later than that in males, so that late paraphrenia may still be part of the same continuum. As the relationship between paraphrenia and schizophrenia remains in dispute, an investigation into potential genetic markers of paraphrenia might shed some light on the aetiology of the disorder, and contribute to our knowledge of its nosology.

Certain antigens of the HLA (Human Leucocyte Antigen) Complex have been shown to be associated with susceptibility to disorders such as ankylosing spondylitis (B27), rheumatoid arthritis (DR4) and diabetes mellitus (DR3 and DR4). There has also been considerable interest in the possible association between HLA antigens and the major functional psychoses (Goldin & Gershon, 1983). Although for schizophrenia as a whole the results of studies have been conflicting, there has been virtually complete consistency in the finding of an association between HLA-A9 and paranoid schizophrenia (McGuffin *et al*, 1981; Ivanyi *et al*, 1983). Moreover, HLA-A9 was also found to be markedly increased among older schizophrenics (Eberhard *et al*, 1975), but no studies, to our knowledge, had attempted to examine HLA antigen associations in late paraphrenia.

Method

Thirty-one unrelated British patients, 29 females and two males, were HLA typed; this formed part of a larger study on the possible role of organic factors in the genesis of the syndrome. The ages of the patients ranged from 61 to 88 years, with a mean of 74.96. HLA-ABC typing was done by a modified two-stage NIH technique (Festenstein *et al*, 1973); HLA types were assigned on the basis of reactions with a panel of at least 180 local and workshop sera. The frequencies of the HLA antigens of the patients were compared with those of an unrelated British control panel of 187 individuals (average age 35).

Patients were first diagnosed as paraphrenic by the consultant psychiatrist in charge of their case, but before inclusion in the study, all were assessed using the Geriatric Mental State schedule (GMS) (Copeland *et al*, 1976) and a detailed psychometric procedure. Subjects were required to fulfil the following criteria: (1) presence of fantastic, persecutory, grandiose delusions; delusions of reference and hallucinations; (2) absence of a primary affective disorder; (3) intellectual capacity in keeping with that of normal ageing; (4) phenomena occurring in a setting of clear consciousness; (5) first onset of paraphrenia at the age of 60 or over; (6) absence of a history of cerebrovascular accident, neurological disorder, or alcoholism.

The software used to analyse the HLA data was developed by Dr J. D'Amaro, Department of Immunohaematology, Leiden, The Netherlands. The significance of differences in antigen frequencies between patients and controls was assessed by the method of Woolf (1955), with the modification of Haldane (1955). The aetiological fraction (Green, 1982), which estimated the degree of contribution of an antigen to the development of a disease, was also calculated.

Results

The antigen frequencies are shown in Table I. When compared with the controls, the paraphrenic patients showed increased frequencies of BW55, B37, and CW6, significant at the 0.05 level before correction for the number of comparisons. These differences became non-significant both after correction for the number of comparisons (43) (Svejgaard *et al*, 1975) and after Edwards' (1974) correction, which is slightly less conservative, was applied.

Neither A9 nor its splits (A23 and A24) were significantly increased in frequency in the patients.

Discussion

The question whether the positive HLA antigen associations found in this study are in fact due to the disparity in age between the controls and the patients can probably be answered in the negative, as no changes in HLA profile with ageing have been reported (Blackwelder *et al*, 1982).

The lack of an association with A9 antigen suggests that patients with late paraphrenia may be biologically different or genetically distinct from schizophrenics. Funding (1961), reviewing his data on 148 patients in whom paranoia developed after the age of 50, concluded that paraphrenia, if it is inherited, is transmitted in a manner different from that of schizophrenia. A similar opinion was also expressed by Retterstol (1968), who concluded in his consideration of data on the subtyping of monozygotic twins and schizophrenia that later-onset paranoid forms of schizophrenia may be inherited in a manner distinct from that of other subtypes of schizophrenia.

In this study, the sample size was too small to refute confidently an association with A9. We have calculated that if the relative incidence of the disorder in A9-positive versus A9-negative individuals is approximately two, and if about 15% of the controls carry the marker trait, the sample size required to detect an association significant at the 5% level would be 105. Nevertheless, there was not even a trend towards A9 associations appeared in our data. It is therefore unlikely that we are commiting a type II error. Of the three HLA antigens with which positive associations were found in this study (BW55, CW6

and B37), the most likely to be relevant is B37. HLA B37 has the lowest (uncorrected) P value for the χ^2. Also, as CW6 is in linkage disequilibrium with B37 in caucasoids, its increased frequency is likely to be secondary to that of B37. If the primary association of paraphrenia were with CW6, one would have expected an increase in other HLA-B locus antigens in linkage disequilibrium with it (i.e. B13, BW47, BW57, BW50), as is the case in the only CW6-associated disorder so far described—psoriasis (Tiilikainen *et al*, 1980).

We can conclude that since B37 and CW6 are in positive linkage disequilibrium in European caucasians, our results probably represent an increased frequency of these two antigens simultaneously in the patients investigated. This finding merits further investigation. The best way to proceed would be to repeat the study in an independent sample. The B37 association, if confirmed, would make possession of this antigen the strongest known risk factor for developing the disorder.

Prolonged Oculogyric Crisis on Addition of Nifedipine to Neuroleptic Medication Regime

Extrapyramidal symptoms, including oculogyric crisis, are well recognised side-effects of clopenthixol medication, but precipitation of prolonged oculogyric crisis on addition of nifedipine to an ongoing clopenthixol regime has not so far been reported.

Case Report

The patient, a 26-year-old-single person, is a long-stay resident at Leavesden Hospital. He suffers from disintegrative psychosis with infantile autism, probably following infantile convulsion when aged 18 months; he is extremely anxious. His principal problems are self-injurious behaviour, in the form of eye poking, aggressive outbursts directed towards others and stereotyped ritualistic behaviour. In addition to behaviour modification, he had been treated with chlorpromazine 50 mg *q.d.s.* and clopenthixol 400 mg i.m. fortnightly for 2 years. In 1983 he was found to have idiopathic hypertension, BP 160/130 mmHg; he was investigated but no cause was found for his hypertension. He was treated with atenolol 100 mg daily, which had to be stopped on 17 June 1984, as he developed an allergic reaction in the form of wheezing and eye irritation. He was prescribed nifedipine 10 mg *t.d.s.* 2 days later, but after 1 week he became extremely drowsy and nifedipine was stopped and chlorpromazine reduced to 50 mg *b.d.* Within 3–4 days he was alert again and able to attend school. He had his last injection of clopenthixol on 28 July 1984; one week later nifedipine was recommenced and the very next day he developed oculogyric crisis (eyes were permanently fixed in upturned position), which failed to respond to i.m. injections of procyclidine up to 60 mg daily. One week later nifedipine and neuroleptic medication were stopped, and 3 days later oculogyric crisis again subsided. Neurological examination did not reveal anything significantly abnormal. During this episode his blood pressure remained between 150/110 mmHg–130/100 mmHg. To the time of writing (6 months) he has been taking chlorpromazine 600 mg daily and captopril 12.5 mg *b.d.* without any untoward effects.

Discussion

Nifedipine is a potent calcium antagonist. Its most important effect is to protect the heart against excessive oxygen utilisation. It also causes peripheral vasodilatation. Its known side-effects are throbbing headache, flushing and dizziness, tachycardia and peripheral oedema. It is known to interact with digoxin and β-adrenergic receptor blocking agents, but there are no reports of the type of adverse reaction seen in our patient. He has not been given nifedipine or clopenthixol again for fear of precipitating another oculogyric crisis. As we did not use nifedipine on its own, it cannot be assumed that the prolonged oculogyric crisis was due to nifedipine but it appears probable that nifedipine potentiated the extrapyramidal symptoms of neuroleptic medication. It may be that the interaction has something to do with the calcium antagonist properties of nifedipine. It is perhaps of interest that diltiazem, another calcium antagonist vasodilator, has been reported to produce akathisia (Jacobs, 1983).

Acknowledgement

I thank Dr Isweran, Consultant Psychiatrist, for permitting me to send this case for publication.

The Continuum of Psychosis and the Gene

SIR: Crow (*Journal*, October 1986, **149**, 419–429) appears to fall into the trap, common to most discussions of unitary psychosis, of regarding psychosis or psychoses as disease(s) rather than syndrome(s). As a result, he is led to postulate the existence of a peculiarly unstable gene or limited set of genes whose abnormalities express themselves as psychosis of varying symptomatology.

That schizophrenia is a syndrome has been recognised ever since Eugen Bleuler wrote about "the schizophrenias", and the evidence that they have multiple aetiologies is now fairly compelling. Of particular relevance to Crow's argument is the finding that process schizophrenias may have a rather low heritability relative to some other types. Severe depression, also, seems to have multiple causes and it is probable that mania has more than one cause (it appears that, in a small number of families, its inheritance is X-linked while in most families it is not; some patients may have abnormal vanadium metabolism; some patients respond well to lithium while others do not, etc.). In situations like this, the observation of continua between syndromes is to be expected and has no great aetiological significance. After all, high dose steroids can produce depression in one patient, mania in another and paranoid schizophrenia in a third. It would be most interesting to know the reason for these idiosyncrasies, but they would hardly justify postulating the existence of a special 'steroid psychosis' gene with unique properties.

It would not be difficult to construct an argument similar to Crow's, centering around bellyache. There is considerable overlap in the symptoms and other characteristics of people suffering abdominal pain, and it may well be the case that children of women with gallstones are prone to develop diverticulitis (as a result of common nutritional habits). Equally, there are probably seasonality effects in bellyache since it is likely to be more common at Christmas time and over the summer holiday period. Perhaps, therefore, there is a bellyache gene similar to the proposed psychosis gene. There are no doubt genes controlling cerebral organisation and dominance effects which may one day be of great interest to psychiatrists especially, I suspect, those studying personality disorder, but existing knowledge is insufficient to enable one to say anything of heuristic value about them.

SIR: Crow is to be congratulated on his imaginative theory of psychosis (*Journal*, October 1986, **149**, 419–429). One thing puzzles me about his use of the season of birth data to support a viral explanation. His Figure 2 certainly shows, consistent with the hypothesis, that there is an excess of births in patients with psychotic illnesses during the winter months. However, it also shows an equally large *reduction* during the summer months, a phenomenon that seems to be difficult to reconcile with the presumed pathogenic effects of a virus.

There are several equally convincing explanations of the season of birth effect, one being that it reflects the cycles of sexual activity among the parents of future psychotic patients. Might this not be a more credible and parsimonious explanation of the data, given that there is no other evidence for the viral theory?

Chronic Schizophrenia and Long-term Hospitalisation

SIR: It was good of Abrahamson (*Journal*, September 1986, **149**, 382) to notice *Institutionalism and Schizophrenia* (Wing & Brown, 1970), but I wonder if I could persuade him to re-read it? He will find that we did not describe one pattern of relationship between negative aspects of behaviour in schizophrenia and length of stay in hospital. There were three, a different pattern for each of our hospitals. More important, our conclusions about the influence of social environment were not derived from these results. On the contrary, we stated (p. 12) that there was overwhelming evidence against the "startling assumption that length of stay is in any way significant as a measure of severity of illness".

What we did find was that when age and length of stay were standardised, patients in the hospital with the poorest social conditions still had the most severe deficit. Moreover, when twenty patients from each hospital, matched for age, length of stay, clinical condition, negative score and attitude to discharge, were compared, major differences remained between the social environments provided for them by the hospitals.

Among much other evidence provided, Abrahamson may be surprised to read that this was not just a cross-sectional study but involved repeated observations over a period of eight years. The social withdrawal scores rated at the beginning and end of that time were highly correlated and showed a mild average improvement in those who remained in hospital. His observation that schizophrenic patients do not necessarily deteriorate thus replicates ours. However, we did measure an increase in 'social poverty' in two of the hospitals during certain periods of observation, with a concomitant increase in 'clinical poverty'.

We pointed out that surveys of this kind could not provide definitive tests of the three kinds of theory stated in chapter 1, but this unit has provided a series of other studies, some of them experimental, that strongly support an interactive socio-medical model. Abrahamson might be particularly interested in an experiment involving very severely impaired patients (Wing & Freudenberg, 1961). They were not impervious to further social stimulation, the problem was to maintain improvement once it was withdrawn.

Gluten Sensitivity in Schizophrenia

SIR: Vlissides, Venulet & Jenner (*Journal,* April 1986, **148,** 447–452) have concluded that gluten sensitivity is of little importance for schizophrenia in general. This far-reaching conclusion is based on a study which is methodologically unsound and, at best, inconclusive.

The difficulty in interpreting the data on quite remarkable patient improvement noted after the switch from pre-trial hospital diet to gluten-free diet is a case in point. Five parameters showed statistically significant improvement: psychotic disorganisation, retardation, hostile belligerence, anxious depression, and depressive mood. No significant worsening was noted on any parameter. Judging from Figure 1, several of the remaining seven PIP dimensions may well have registered significant improvement under gluten-free diet had one-tailed (directional) statistical tests been performed, which is the appropriate statistical technique since a specific hypothesis was under investigation. However, regardless of the statistical method, one is unable to determine whether the data reflect treatment effect, observer bias or a placebo effect because the period before gluten-free diet was non-blind and there was no parallel control group. The subsequent period of gluten challenge did not do much to resolve the issue because possible observer bias arising from knowledge of the sequence of treatments and the time series effects were not controlled. More importantly, the research design did not permit a consideration of the possibility that the six week gluten challenge, while not worsening psychopathology to base-line values, may well have had enough adverse effect in the time period to arrest therapeutic progress. In the AB research design used, this would show up as 'no change', whereas in the ABA design used in the Singh & Kay (1976) study, such an adverse effect would very likely have been detected.

The authors attributed the clinical improvement in patients to the attention they received during the study, or what would generally be described as a placebo effect. Within the framework of their study design, such a conclusion would be no more valid than that suggesting an active treatment effect of gluten exclusion. To the contrary, sustained improvement of a highly chronic and treatment-resistant group of schizophrenics lasting over 3 months due to mere attention or placebo effect would be highly implausible indeed.

The study is also open to criticism because of the patient sample used. While the hypothesis being tested relates to schizophrenia, 7 of the 24 patients in the study had other diagnoses. Of the 17 schizophrenics, only one had a diagnosis of non-paranoid schizophrenia, which is the classification suggested by previous work to be at greater risk for gluten sensitivity (Singh, 1979). On top of that, the population was highly chronic and one in which likelihood of response to any form of treatment would be small.

We conclude, therefore, that the study is not a valid test of the gluten hypothesis of schizophrenia and that the conclusions reached by the authors with regard to the hypothesis are not warranted. In an area of such importance as schizophrenia, this hypothesis represents one of the few viable notions of aetiology and a new treatment approach. It deserves to be investigated thoroughly and with carefully designed studies in which adequate provisions are made for the heterogeneity of this condition (Singh & Kay, 1976; 1983).

Psychiatric Disorder in the General Hospital

SIR: Mayou & Hawton (*Journal*, August 1986, **149**, 172–190) are right in asserting that there have been few systematic studies about differences in the prevalence of psychiatric disorder in the many types of in-patient and out-patient units within the general hospital. The paucity of data is most apparent in the setting of emergency departments. In a descriptive study of psychiatric emergencies in a general hospital setting, we studied 352 patients presenting psychiatric emergencies over a four-month period (1.86% of all attenders). Only 26 (7.4%) of these patients were already registered with the outpatient services of the psychiatry department, the rest being new patients. The case detection increased by 550% with the continuous presence of a psychiatrist in the emergency room—in contrast to "on-call' cover. Inaccuracies of identification were made by non-psychiatric physicians in approximately 14% of cases. Despite detection, physicians had the tendency not to refer patients to the psychiatrists-on-call. In only 34% of the patients screened, were the non-psychiatric physicians able to make a correct diagnosis of the psychiatric illness. In two-thirds of all patients, non-psychiatric physicians were unable to suggest any management for the psychiatric emergency.

Males outnumbered females in a ratio of 2:1. The majority of the patients (77%) were referred to emergency services by relatives and friends or patients themselves. Two-thirds of the patients were brought owing to the severity of the clinical condition and the rest, one-third, for medico-legal and social reasons. Approximately 80% of our patients sought consultation within one month of the onset of the illness episode. About 40% of those using psychiatric emergency services had long-standing problems of more than one year's duration. Only 10% had a history of hospitalisation for psychiatric illness in the past; and only 20% of the patients had visited emergency services more than once in the past one year. Thirty-one per cent had neurotic disorders, 26% had functional psychotic illnesses and 18% had alcohol-related problems.

There is considerable psychiatric morbidity in the emergency-rooms of general hospitals, much of which is unrecognised by non-psychiatric physicians. There is a need for improved research designs in studies of the epidemiology of psychiatric emergencies in general hospital settings, as psychiatric emergency services represent one of the chief entry points into the network of mental health services.

Hydroxylated Metabolites of Tricyclic Antidepressant in the Elderly

SIR: We read with interest the report by Kutcher *et al* (*Journal*, June 1986, **148**, 676–679). These findings are consistent with our own experience with nortriptyline in a similar population.

Like 2-hydroxydesipramine, the 10-hydroxylated metabolite of nortriptyline is pharmacologically active (Bertilsson *et al*, 1979). In elderly depressed patients, average unconjugated plasma concentrations of 10-hydroxynortriptyline are higher than in younger patients taking equivalent doses, despite comparable concentrations of plasma nortriptyline (Young *et al*, 1984). There are also marked inter-individual differences in plasma 10-hydroxynortriptyline/nortriptyline ratio in this population. We reported development of symptoms and signs of congestive heart failure in an elderly patient with moderate plasma nortriptyline concentrations but high plasma 10-hydroxynortriptyline (Young *et al*, 1984). We also noted that, in 18 geriatric depressed in-patients, plasma 10-hydroxynortriptyline concentrations or combined plasma 10-hydroxynortriptyline and nortriptyline concentrations, but not plasma nortriptyline concentrations alone, differentiated those patients who developed quinidine-like effects during treatment (Young *et al*, 1985).

Taken together, our own preliminary findings and those of Kutcher *et al* suggest that further study of hydroxylated metabolites of tricyclic antidepressants is warranted in geriatric patients. Their contribution to toxic and therapeutic effects, and to changes in neurobiological measures during treatment, are open to further investigation; these issues might be studied to advantage in elderly patients.

Diagnostic Value of Schneider's First Rank Symptoms in Schizophrenia

SIR: Kurt Schneider (1959) claimed that certain "first rank symptoms" (FRS) were pathognomonic of schizophrenia in the absence of organic brain disorder. Recent investigations have argued against this assertion, but most of the studies have considered FRS collectively and the value of individual symptoms has not been explored much. The frequency of FRS in schizophrenics ranges from 28–72% (Mellor, 1982). This variation is probably due to differences in the diagnostic criteria used and methods employed in eliciting FRS.

We conducted a pilot study based on fifty consecutive admissions to evaluate the prevalence and diagnostic implications of FRS. All the patients, irrespective of their diagnosis, were interviewed by one of the authors (MG) for the presence of FRS as early as possible after admission. The findings were recorded on a questionnaire specially prepared for the study and based on Mellor's definitions of the FRS. The patients were later seen by the first author (HDC) to confirm the findings and diagnosis. Diagnostic labels were given according to DSM-III (1980).

The distribution of 50 patients (23 males, 27 females; age range: 21–86 years) according to the diagnostic categories was as follows: schizophrenic disorders 24; psychotic disorders not elsewhere classified 6 (schizophreniform disorder 2, brief reactive psychosis 1, schizoaffective disorder 1, atypical psychosis-schizophrenia onset after age 45, 2); affective disorders 9 (mania 2, major depression recurrent 4, atypical depression 1, dysthymic disorder 1); organic mental disorders 3; anxiety disorders 2; adjustment disorders 5; and personality disorders 2. FRS were present in 26 patients distributed as follows: schizophrenic disorders 17; psychiatric disorders not elsewhere classified 4; affective disorders 2; organic mental disorders 2; and personality disorders 1.

The analysis of data on schizophrenics with FRS produced the following results. (a) The majority of patients with schizophrenia had 2 or more symptoms, maximum 9 symptoms; only 3 had 1 symptom each. (b) The symptoms more commonly reported (in order of frequency) were: 'made' affect (11), thought insertion (10), thought broadcasting (9) and voices arguing (7). (c) Auditory hallucinations were reported by half the patients, the commonest being voices arguing, but always accompanied by a symptom of passivity. (d) 16 patients with schizophrenia had one or more passivity experiences. (e) Delusional perception was reported only by 3 patients. (f) The commonest association between any two symptoms was between thought insertion and thought broadcasting.

The findings suggested that FRS, though observed in other disorders at times, were much more common among schizophrenics. Passivity phenomena were the commonest. Auditory hallucinations alone were of no diagnostic value. Similar observations were made in patients with schizophreniform disorder and schizophrenia after the age of 45.

Folate and Vitamin B_{12} in Eating Disorders

SIR: We investigated serum folate and vitamin B_{12} in a series of patients with eating disorders in comparison with an age-matched group of normal subjects, and examined the relationship between their deficiency and the presence of depressive symptoms and weight loss. Forty-five female anorectic outpatients (cross-section study), nine of whom were in-patients (longitudinal study) were studied. Folate and vitamin B_{12} levels in this group were compared with their levels in 7 normal weight bulimic patients and 14 normal controls. Anorectic patients showed severe folate deficiency (less than 1.0 ng/ml) in 37% of cases, a significantly greater rate than that of bulimic patients (14%) and normal controls (11%) ($P<0.01$). There were no significant differences between rates of vitamin B_{12} deficiency (less than 150 pg/ml) between anorectics (22%), bulimic patients (14%) and normal controls (11%). Fifteen anorectic patients who were assessed to have mild depression (Hamilton Rating Scale score of 10 or above) showed a trend for lower folate concentrations than those with HRS less than 10 ($P<0.07$). There was no association between folate levels and weight in the anorectic group. Patients studied in series showed an increase in folate levels in association with their increased weight and fewer depressive symptoms. In one patient who had 10 folate estimations there was a significant correlation between folate levels and HRS scores ($r=-0.7$, $P<0.05$). Anorectic patients who were receiving psychotropic medication had a significantly greater rate of folate deficiency than those who were drug-free, an association that was mediated by greater affective morbidity exhibited by the former group. These findings further confirm the association of folate deficiency and depressive symptoms in a group of patients with anorexia nervosa, highlighting the role of folate in the regulation of mood (Reynolds & Stramentinoli, 1983; Abou-Saleh & Coppen, 1986).

Koro in an Israeli Man

SIR: I read with interest the Modai *et al* Case Report (*Journal*, October 1986, **149**, 503–506), adding another patient to the literature of Koro among non-Chinese subjects. These authors stated that there are only eight case reports of Koro from the Western hemisphere. I wonder what is the demarcation of their western hemisphere, because in 1984 features of Koro-like symptoms among 16 subjects culturally unrelated to China or Indonesia were discussed by Berrios & Morley (1984). Since then five more patients have been reported: (Ang & Weller, 1984; Emsley 1985; Moodley, 1985; Oyebode *et al*, 1986) making a total of 21. Even though Modai *et al* presented a primary Koro patient, I am not convinced of the typicalness of their patient: because of 22 non-Chinese subjects (including the authors' case) only Barrett's (1978) patient presented with all Koro symptoms i.e., (1) shrinking of the penis; (2) into the abdomen; (3) associated with fear of death. Lapierre's (1972) patient presented with shrinking of penis associated with fear of death and the remaining 20 patients presented with only shrinking of the penis.

Book Reviews

Editor: Sidney Crown

Psychological Medicine: An Introduction to Psychiatry (10th edition). By PETER STOREY. Edinburgh: Churchill Livingstone. 1986. Pp. 484. £12.95.

This is the tenth edition of the well known textbook for students, founded in 1943 and for many years known as "Curran and Partridge". Partridge died in 1984, and Sir Desmond Curran has died since this edition went to press, so the enterprise is now Storey's, and has been brought up to date.

The introduction has the flavour of civilised commonsense, plus great experience. The author is excellent at explaining how and why psychiatry is part of medicine, and other personal themes include the great importance of work in people's lives and the limiting effect of constitution, as opposed to physical and psychological causes of disorder, in damping enthusiastic claims of cures. The general chapter on aetiology is an excellent essay on the subject. It is followed by a chapter on symptoms and the author's classification (clear and reasonable, but there is no mention of ICD-9 or DSM–III) and then by one on case taking.

The chapters on illnesses are in general as up-to-date and thorough as they should be at this quite extensive length for a students' book (although trazodone is still in use and involutional melancholia being diagnosed). There is a separate chapter for general aspects of treatment, and it is noticeable that physical methods (ECT is allocated 6 pages, and psychosurgery 5 pages) are well covered, perhaps more enthusiastically than psychotherapy, which nevertheless gets 20 pages. Behaviour therapy and cognitive therapy are covered very briefly.

There is a new chapter on psychosomatic conditions, and extensive updating on anxiety, hysteria and mental handicap. There is no coverage of child and adolescent psychiatry. The chapter on the law covers thoroughly the Act of 1983 in England and Wales, and 1984 in Scotland.

The style is conversational and readable, the text well printed, the reading list poor and unrevised, and the index excellent. Overall, the standard of earlier editions is well maintained, as befits one of the best general textbooks.

ANDREW C. SMITH, *Consultant Psychiatrist, Greenwich District Hospital, London*

Family Approaches to Major Psychiatric Disorders. Edited by MELVIN R. LANSKY. Washington: American Psychiatric Press. 1985. Pp. 147. $12.00.

This book is a collection of papers from a symposium entitled "Family Therapy and Major Psychopathology". The central themes for the papers arose from an earlier book in which warnings were given about the dangers of splitting off family therapy from other therapeutic interventions. The main theme is therefore about integration of various therapeutic approaches which take account of the patient, the family and the wider systems. A second and related theme is to highlight for each major disorder the special problems presented.

The editor in his excellent introduction traces the historical and psychological development of family therapy. He sees family therapy as having recently gone through its rebellious adolescence, thumbing its nose at boring old psychoanalysis and conservative psychiatry. Now in its maturity, family therapy is ready to manage its own identity and allow the identity of others and therefore be one of several integrated treatments.

It is a short collection of only six papers, each emphasising the need to serve the interests of the patient and his family in whatever way seems best. In the first paper on the Narcissistically Vulnerable Marriage, Lansky gives a clear account of the use of psychoanalytic understanding in family therapy. The chapter on alcoholism highlights the special problem of abstinence and the multifaceted nature of the disorder with its genetic background and relationship to depression and the social, cultural and family factors. Each paper has something special to offer. The one on bipolar marriages emphasises the crucial role of medication, especially since it makes the patient and his family more amenable to psychotherapy and multiple family group therapy. The now familiar psycho-educational approach in schizophrenia is reviewed and described verbatim in an appendix. The role of education is again seen as part of an ongoing family treatment plan.

The last two papers are on organic brain syndrome and cancer. Both describe not only the traumatic effects of these conditions on families and patients but how they may emphasise pre-existent pathological patterns. Family treatment is seen as vital in both cases but needs to be combined with that of the health care systems. The paper on cancer determinedly and touchingly emphasises life as much as death.

I found this an interesting and sensitive book. The authors emphasise the stress and burden of chronic illness as well as the need to be extremely careful about inducing guilt in families. They also pay particular attention to their own countertransference.

This book is well worth reading and is to be recommended to all those who work with these extremely difficult problems.

RUTH BERKOWITZ, *Associate Research Fellow, MRC Social Psychiatry Unit, London*

Self Injurious Behaviour: A Collection of Published Papers on Prevalence, Causes, and Treatment in People who are Mentally Handicapped or Autistic. Edited by GLYNIS MURPHY and BARBARA WILSON. Kidderminster: BIMH Publications. 1985. Pp. 455. £19.95 (hb), £9.95 (pb).

This is a valuable book that brings together a collection of 54 previously published papers extensively covering the topic of self-injurious behaviour in mentally handicapped and/or autistic individuals. It is divided into three sections, dealing with the areas of prevalence, development and maintenance of self-injurious behaviour and treatment. Each section is subdivided and covers such areas as animal studies, self-injury in non-handicapped individuals, and various hypotheses that have been proposed to explain such behaviour.

Why people who are mentally handicapped or autistic injure themselves is not known, but between 5 and 15% exhibit this form of behaviour at some time in their lives. The papers in this book examine a series of hypotheses including developmental aspects, the role of infections (e.g. otitis media), sensory stimulation as reinforcement, learned behaviour and psychodynamic views. The main message of this collection of papers is that proper evaluation and observation is essential before, during and after intervention whether this be behavioural, medical or the use of protection. What initiates the behaviour may well be different from what perpetuates it, and what has been shown to diminish behaviour in one circumstance may well increase it in others. There are also clearly ethical issues to be considered, particularly with adversive therapies, and the danger that the emotional impact of the self-injurious behaviour on others (care staff and family) may precipitate them into ill-informed and inappropriate treatments. This book is an excellent reference work but is not a guide to management. In the introductory sections there is discussion concerning management and many of the papers deal with treatment issues, but there can be no substitute for experience and careful thought when it comes to the treatment of such difficult behaviour problems.

Self-injurious behaviour can occur in a variety of handicapping conditions but its association with the Lesch Nyhan syndrome is particularly perplexing. The papers by Nyhan and others illustrate how varied the degree of handicap and how severe the behaviour can be. The largest number of treatment papers deal with the use of psychological techniques. Properly applied these clearly can be effective, but some papers report single cases and how well such treatment can be generalised to other circumstances is questionable.

Readers of this book have to be critical and selective but this is undoubtedly a valuable reference work in an area of study neglected by many professionals.

A. J. HOLLAND, *Lecturer*
Institute of Psychiatry, London

Job's Illness: Loss, Grief and Integration. A Psychological Interpretation. By J. H. KAHN. London: Royal College of Psychiatrists. 1986. Pp. 232. £10.00.

The *Book of Job*, and in particular its titular hero, Job himself, have for ever been the subjects of heated debate among Talmudists and theologians. The manifest problem posed is: how is it possible for the life of a man like Job, a man of unsurpassed generosity and piety, to be suddenly shot through with the heavy artillery of disaster, transforming it into a personal hell? There are those scholars, Talmudists included, who would maintain that Job never existed, and that the narratives in the drama are allegorical and devised to answer the burning question: "why is it the righteous who suffer? Why are the innocent slaughtered?".

The pages of history are repeatedly stained with soul-searing illustrations. Take as recent examples the victims of the chemical disaster at Bhopal, and, even worse, those who died or will inevitably die as a result of the Chernobyl nuclear catastrophe; or the countless thousands dying of famine in Ethiopia and elsewhere. Go back forty years or so and ponder the obscene maltreatment of Jews and other innocents in Hitler's Germany and Stalin's Russia. All these helpless victims – the list is never-ending – are entitled to share the agony of Job; like him they are lost in a meaningless universe and abandoned by their God or gods. The answer to the problem, persuasive in its simplicity, is to be found in the allegory, namely, that man must rest in faith and resign himself to the mysterious and, offentimes, incomprehensible ways of God.

The allegorical explanation is, however, rejected by some scholars, including Dr Kahn, the author of this book. He, a practising psychoanalyst whose cultural roots are steeped in the Judeo-Christian tradition, is eminently qualified to explore an alternative explanation. He insists that there is a valid psychological interpretation.

Dr Kahn argues that Job was a real person who, apart from his somatic complaints, suffered from a combination of three psychiatric syndromes; obsessional neurosis, paranoia, and, most importantly, depression. The book, he infers, is in effect a case history of Job's complex illness offering to its readers an insight into its aetiology and treatment, the latter, incidentally, including something akin to what today would be called group therapy.

For myself, I have to confess that I am unconvinced by Dr Kahn's argument; but, then, I am an unbeliever in both the biblical and psychoanalytic sense. Nevertheless, I would be the first to acknowledge Dr Kahn's profound scholarship and would salute the courage of his undertaking.

It should be added that his book was first published in 1975 by Pergamon, and the College is to be congratulated for being the means whereby a second edition of such an intensely stimulating piece of research is again made available.

HENRY R. ROLLIN, *Emeritus Consultant Psychiatrist, Horton Hospital, Epsom*

Study Guide and Self-examination Review for Understanding Human Behaviour in Health and Illness. 3rd edition. By MARITA J. KEELING and RICHARD C. SIMONS. London: Williams & Wilkins. 1986. Pp. 348. £13.00.

This is an attractively laid out book consisting of questions (mostly multiple choice), answers and explanations. Although the questions are generally of a high standard, unfortunately none of the multiple choice type follows the multiple true-false format used predominantly in medical examinations in this country.

Clearly, the book will be of most value when used in conjunction with its parent text (Simons, 1985), a book aimed primarily at medical students. Herein lies another possible limiting factor, because I suspect that the parent book is not widely used or available in this country. This is in some ways a pity because, having had a look at it, I find it impressive in its attempt to integrate clinical aspects of behaviour and the basic sciences and so make the former more comprehensible. However, it does have a strong transatlantic flavour as evidenced by, for example, the choice of references and, perhaps as a result of so much psychology being included, the psychiatry sections are rather scanty.

On the positive side, however, the question book has a strong appeal which stems from the philosophy of the parent text and lies in its coverage of topics often neglected. For instance, subjects covered include the nature of the doctor-patient relationship, the 'difficult' patient, psychological reactions to pain and physical illness, pregnancy, grief and mourning, sexuality, the dying patient, work and creativity.

Alas, I think the limitations I have mentioned will outweigh the positive features for most medical students and trainee psychiatrists in this country, although I think it and the parent textbook are reasonably priced at £13 and £26 respectively. Libraries, however, could usefully stock both books.

ROGER FARMER, *Consultant Psychiatrist, University College Hospital, London*

Alcohol, Drugs, and School-Leavers. By MARTIN A. PLANT, DAVID F. PECK and ELAINE SAMUEL. London: Tavistock. 1985. Pp. 190. £16.95.

This book is about a group of fifteen to sixteen year-old Scottish school children, whose use of alcohol and other psycho-active drugs was followed up for four years. The research project was originally conceived as being solely an alcohol study, but during the course of the study illicit drug use and tobacco smoking were also investigated. The aims of the original research project were, firstly, to determine whether knowledge, attitude and behaviour concerning alcohol among school leavers predict subsequent alcohol-related behaviour, and secondly, to find out whether educational programmes meet their objectives. With regard to the second aim, since none of the schools provided alcohol education in a systematic or elaborate way, it could not be adequately measured, and therefore the study cannot be regarded as a very useful evaluation of alcohol education. With regard to the first aim, the study was more interesting. It found that future alcohol use was not predicted by the student's knowledge, attitudes or behaviour concerning alcohol. However, both high alcohol consumption and alcohol-related consequences were highly correlated with *not* being brought up by the natural father and mother. I found much of interest in this book, both as a Consultant Psychiatrist specialising in alcohol problems, and also as a School Governor. In my particular school, I have used my psychiatric skills not in direct alcohol education, but indirectly by devising courses in human relationships to help the young people to prepare for marriage, in the belief that helping young people to turn to other people will make them less likely to turn to alcohol. If in addition these courses succeed in helping young people to form stable marriages, then alcohol problems in the next generation should be reduced. This book confirmed my view that in the present state of knowledge, alcohol prevention by such indirect methods is likely to be more fruitful than direct alcohol education in schools.

T. A. Spratley, *Consultant Psychiatrist, St Martins Hospital, Canterbury*

Advocacy and Empowerment: Mental Health Care in the Community. By Stephen M. Rose and Bruce L. Black. London: Routledge & Kegan Paul. 1985. Pp. 231. £29.95.

This book documents the problems of discharged, institutionalised patients from psychiatric hospitals in New York State. These problems, for example 'the revolving door', will be familiar to those working in the British context, though the volume and intensity of the difficulties may be less than in the American situation. The authors indict the change from hospital to community care as being merely 'a drift in the locus as opposed to the focus of the mental health delivery system'. It is argued that there was a failure to transfer funding from the State Hospitals to community care as the former were being run down. Of more importance to the authors is the carry over of the medical model of care from the hospitals to the community. There follows a fairly standard diatribe against medical hegemony during which almost every noun with negative connotations is used.

The alternative approach, proposed and described by Rose and Black, for ex-patients in the community is a somewhat confrontational one known as 'advocacy and empowerment'. This is based on the theories of a number of sociologists and educators. In essence, it involves an understanding by the worker of the client's behaviour and view of the world in the light of experiences within the psychiatric system. The relationship built up between worker and client is used to help the client to become active and creative in gaining the knowledge and skills for life in the community. Confidentiality criteria for workers are strict but the relationship with the client usually gives rise to authorisation for the worker to advocate on the client's behalf. Since this approach starts from the assumption that clients are oppressed persons as a result of their experiences, advocacy often leads to conflict with other more conventional agencies.

The book is strong on theoretical perspectives, principles, frameworks, processes and programmes, yet examples from practice are few and, when given, tend to be 'snapshots' relating to uncoordinated issues. The book lacks case histories which might over a period of time in the life of a client illustrate the benefits of the advocacy/empowerment approach. This seems particularly important since, although objective evaluation strategies are described and criticised, no results are forthcoming. A lingering impression remains that the principal driving force is the commitment to the ideology.

Donald P. Forster, *Senior Lecturer in Community Medicine, University of Newcastle upon Tyne*

Pharmacological and Behavioural Treatment: An Integrative Approach. Edited by Michel Hersen. New York: John Wiley. 1986. Pp. 400. £45.50.

This book is one in a large series on Personality Processes, the emphasis of which is principally on psychological aspects of assessment and management of various types of personal problems and psychiatric disorders. This volume seems to emphasise psychological aspects more than pharmacological ones in many chapters. In fact, pharmacological and psychological aspects of management are often discussed separately for a large section of a chapter with only a relatively short section on their combined use, as in the sections on Obsessive/Compulsive Disorder and Neuropsychologic Disorders.

The book is divided into three sections: General Issues, Child Disorders and Adult Disorders. The first section provides a brief review of general issues related to drug treatment, more appropriate for non-medical graduates, a general description of various behavioural techniques and discussion of methods for evaluation of treatment effects. In Child Disorders the value of drug treatment is perhaps overemphasised, particularly with regard to Conduct Disorders and Learning Disabilities. Under Adult Disorders several psychiatric illnesses are discussed in separate chapters: Unipolar Depression, Obsessive/Compulsive Disorder, Phobia and Anxiety, Substance Abuse, Schizophrenia, Psychophysiological and Neurophysiological Disorders. A few of the chapters provide a reasonably critical review of the available literature, such as those on Autism and Obsessive/Compulsive Disorder, but many do not. The chapter on Unipolar Depression, for example, tends to quote references with little critical examination of them and, like many of the other chapters, relies rather heavily on results from single case studies. The chapter on Schizophrenia examines the effects of neuroleptic drugs on psychological functioning and the effects of psychosocial interventions rather than the combination of drugs with behaviour therapy.

Overall, I felt the book was rather weak on living up to its title. Perhaps this is because there is not a wide literature on the combination of treatments? I doubt if this book would be of great value to those with a fairly eclectic training as exists in psychiatry in Britain.

STEPHEN J. COOPER, *Senior Lecturer,*
Department of Mental Health,
The Queen's University of Belfast

Psychotherapy and the Grieving Patient. Edited by E. MARK STERN. New York: The Haworth Press. 1985. Pp. 138. $19.95.

This book was also published as *The Psychotherapy Patient*, Volume 2, Number I, February 1986. It is a collection of essays on diverse aspects of bereavement. It seems quite possible, with tighter editing, to bring the whole volume down to a single article. There is little new inside these pages, and that which is there is perhaps less rigorously presented than we are used to on this side of the Atlantic. Most of the individual 'illustrative' case reports are simply not detailed enough for any objective analysis to be made by the reader of therapeutic method and outcome. Dr Stern, a Professor of Pastoral Counseling, describes the case of Erin, a lady who unfortunately killed herself. One doesn't need to read between the lines to come away with the strong impression that her "bursting with joy" and her inability to recall "a day of sunshine" in her past, together with her excessive drinking, "self-imposed isolation", and her search for "tidbits of hope", not to mention such items as her coffin-buying escapades, just might have responded to lithium or some such alternative medication.

Dr T. L. Brink, co-author of the 'Geriatric Depression Scale', tells us that the ideal therapist is he who is sought out by the client, the ideal therapy depends on factors such as education and degree of dementia, and so on. One cannot help but feel that he has modified his normal way of thinking in order to keep step with the general tenor of the book.

One is fascinated by Edward Tick's catharsis when it comes to his discussion of the "psychohistoric factors affecting the United States people", terminating in a cry for grieving for the Vietnam experience. Undoubtedly Vietnam was a terrible experience for many millions of Americans. My point is that there seems to be some little lack throughout the book of standing back, of not becoming enmeshed in the subjective rationalisations of the patient. The chapter on adult incest survivors, one of the best in the book, is marred by liberal use of snippets of comments made by clients, used to illustrate dynamics that the author wishes to prove, whereas, I feel, fuller case histories would have been more credible.

This volume is a product of American private practice. It is written by authors of many persuasions. There is much modern knowledge about grief which is not contained between its covers, and its references are not reflective of the wider world of thinking. Those on a tight library budget could do worse than look elsewhere.

BRIAN O'SHEA, *Consultant Psychiatrist,*
Newcastle Hospital, County Wicklow, Ireland

The Integration of Neuroscience and Psychiatry. Edited by HAROLD ALAN PINCUS and HERBERT PARDES. Washington: American Psychiatric Press. 1985. Pp. 94. $12.00.

This short monograph is based on the Proceedings of the 1984 Annual Meeting of the American Psychiatric Association, which was devoted to the topic of Neuroscience and Psychiatry.

The chapters provide a graduated sequence from the general to the particular. In Chapter 1, Pardes and Pincus review the new techniques now available for the investigation of brain function, including positron emission tomography (PET), nuclear magnetic resonance (NMR) and brain electrical activity mapping (BEAM). In Chapter 2, Post cites a variety of examples of the application of neuroscience to clinical diagnosis and treatment, including the investigation of affective and schizophrenic psychoses by PET, NMR and BEAM and the introduction of clonidine for opiate-withdrawal and carbamazepine in the treatment of bipolar psychosis. For good measure he adds a brief review of neuropeptides and behaviour. In Chapter 3, Paul reviews recent advances in neurochemistry with particular reference to dopamine and schizophrenia and the role of cholecystokinin as a co-transmitter. In Chapter 4, Wexler, Gusella, Conneally and Housman describe their recent successful application of molecular genetic techniques to the study of Huntington's chorea and face up to the difficult ethical issues involved in its pre-symptomatic diagnosis.

In the final chapter Pincus and Rubinow explore the possibilities for research into the relationship between medical and psychiatric disorders, employing the new data and techniques. A noteworthy contribution is their series of models depicting possible modes of interaction between psychiatric and medical conditions, reminding us that correlation does not necessarily indicate causation.

This small volume provides a brief yet stimulating review of some of the important growing points in biological psychiatry. It will be of particular value to trainee psychiatrists and anyone wishing to keep abreast of this rapidly developing subject.

K. DAVISON, *Consultant Psychiatrist,*
Newcastle General Hospital, Newcastle upon Tyne

Hyperkinetic Children: A Neuro-Psychosocial Approach. By KEITH C. CONNERS and KAREN C. WELLS. London: Sage Publications. 1986. Pp. 160. £19.75 (hb). £10.00 (pb).

This is the seventh volume in the Sage series in Developmental Clinical Psychology and Psychiatry. The authors are two of the best-known American authorities on hyperkinetic children. Publication coincides with the issue of a book covering similar ground edited by one of the leading United Kingdom researchers in the field (*The Overactive Child.* Edited by E. A. Taylor. Oxford: Spastic International). Comparisons are inevitable, in particular because there are such differing views about diagnosis, aetiology and treatment in the USA and Britain. There are many similarities, but importance differences.

Both books are intended to be up-to-date presentations of theory, research and practice for professionals working in the field, whatever their discipline. Both consider concepts of hyperactivity and hyperkinesis, and both review the historical development of the concepts, although this is fuller in the Taylor book. Both consider epidemiology and both draw heavily on research done by the authors or their associates, while reviewing relevant literature. However, the group at the Institute of Psychiatry is engaged in more recent or current research on the topic; their coverage of epidemiology is more extensive, and their review of the work of others more thorough and far-ranging. Both books look at aetiology and examine specific behaviour such as overactivity, attention and impulsiveness, and report on treatment. Conners and Wells are more detailed in their discussion of electroencephalographic research, but for all other aspects the Taylor book is to be preferred. The conclusions drawn by Conners and Wells are usually balanced, and often not vastly different from those of Taylor and his colleagues, but the approach of the latter group is altogether more carefully considered. Furthermore, it is more thorough and enlightening in the elucidation of relevant concepts such as attention and impulsiveness; social aspects receive greater weight, and treatment is reviewed at more length.

The paperback version of Conners' and Wells' book is cheaper and handier but in hardback Taylor's book is less expensive and almost twice as long. Although *Hyperkinetic Children* is in general a readable and sensible account, most professionals would be advised to choose *The Overactive Child.*

ANTHONY D. COX, *Consultant Child Psychiatrist/*
Senior Lecturer, Institute of Psychiatry, London

The Selected Melanie Klein. Edited by JULIET MITCHELL. Penguin: London. 1986. Pp. 256. £4.95.

This is a small but useful book. Juliet Mitchell uses a compact historical approach to demonstrate the development of Klein's work through a collection of key papers, each one prefaced by a short commentary. She is herself a psychoanalyst as well as a feminist. She writes well and in her short introduction she gives some biographical facts and explains certain basic psychoanalytic ideas both from Freud and Klein and highlights the difference between the two. This is an interesting section of the book but it is not entirely satisfactory. She seems uncertain about her readers' understanding of psychoanalytic issues so that on the one hand she carefully explains that dreams and symbols cannot be understood on an *ad hoc* basis and yet on the other speaks about the resolution of the oedipus complex as a result of castration anxiety without any explanation whatsoever of any of these concepts as if everyone should understand immediately what Freud was talking about. She gives some sloppy definitions of concepts such as splitting and projective identification which could spoil a deeper grasp of the issues from the text.

Klein, of course, differs from Freud in many important ways and Juliet Mitchell highlights the difference between Freud's view of the dynamic unconscious as a reservoir of historical repressions contrasted with Klein's view of the internal world as constantly present structuring the individual's internal and external experiences in a much more direct and immediate way, hence unconscious processes including symbols, mental mechanisms and fantasies are far less disguised when compared with the classical viewpoint. The very short introduction, however, did not allow the refinement of these differences, so misconceptions could very easily arise. Although Klein did not see patients as suffering from reminiscences in the same sense as Freud, nevertheless she strongly believed in the memory of pre-verbal experiences which she called 'memories in feeling' and when splitting and projective identification lessen they can be re-experienced in a most extraordinarily detailed way.

In spite of these reservations the book is a valuable contribution which should be enjoyed by psychiatrists interested in psychoanalytic ideas and will be a very useful addition to postgraduate libraries wanting to be representative but not overloaded with large quantities of psychoanalytic works.

P. L. G. GALLWEY, *Consultant Psychiatrist,*
St George's Hospital, London

American Psychiatric Association Annual Review Vol. 5 (Psychiatry Update Series). Edited by ALLAN J. FRANCIS and ROBERT E. HALES. Washington: American Psychiatric Press. 1986. Pp 791. $36.95 (pb), $49.95 (hb).

The fifth Annual Review contains six sections, dealing with (i) *schizophrenia* (section editor, Nancy C. Andreasen): "This section is uncommonly well-balanced and of uniformly high quality. Each chapter is scholarly and careful, yet clinically rich and pleasing to read" (Frederick K. Goodwin); (ii) *drug abuse and drug dependence* (section editor, Robert B. Millman): "presents the latest research from the field's most knowledgeable and experienced psychiatrists" (Lawrence G. Kolb); (iii) *personality disorders* (section editor, Robert M. A. Hirschfeld): "In masterfully written chapters, this section . . . could well stand on its own as a definitive treatise on human personality and its disorders" (John C. Nemiah); (iv) *adolescent psychiatry* (section editors Carolyn B. Robinowitz & Jeanne Spurlock): "The editors selected timely and critical topics . . . The chapters represent essential information in a highly readable style" (George Tarjan); (v) *psychiatric contributions to medical care* (section editors David Spiegal & W. Steward Agras): "an extraordinary collection of essays. They have great depth in the review of diagnostic issues and treatment approaches to the entire gamut of psychosomatic problems" (Paul J. Fink); and (vi) *group psychotherapy:* "without a doubt the best review of the present state of the art of group therapy that I have come across to date. Each of the six chapters is highly informative, sophisticated, and lucidly written. Anyone who practices group psychotherapy or hopes to, should read this section" (Judd Marmor).

The material is less outstanding on international and cross-cultural perspectives and shows a singular regard for DSM-III.

GREG WILKINSON, *Honorary Lecturer,*
Institute of Psychiatry, London

Young Children in Family Therapy. By JOAN J. ZILBACK. New York: Brunner/Mazel. 1969. Pp. 177. $25.00.

This book, a welcome addition to the growing literature of family therapy, is the first dedicated to the specifics of including younger children in family therapy. From the outset, Zilbach draws our attention to the curious position children occupy in family therapy. She contends that younger children are often excluded from therapy sessions and this is reflected in the paucity of literature dealing with children. This book is her attempt to redress the balance.

Zilbach has drawn upon her considerable experience to produce this book. The style is clear and concise. While primarily a practical manual, Zilback has not neglected theory. She presents a selection of quotations from the pioneers of family therapy, such as Ackermann, Satir, Minichin and Whitaker, emphasising the value and necessity of working with the entire family. Zilbach demonstrates with examples how children can promote understanding of family interaction by revealing family secrets in drawing and in play as well as acting, at times, as an ally or co-therapist.

The book is beautifully illustrated, with photographs of sessions and of children's drawings. These are well intergrated into the text of the case vignettes and the therapeutic use of the drawings is made very clear. The author acknowledges her psychoanalytic perspective, but in no case is an interpretation made which is not straightforward and readily understood by the family.

Overall, this is a very good book. It should be recommended reading for those professionals dealing with families with younger children. The author ought to be congratulated not only for informing us of the benefits of working with younger children, but alterting us to the dangers of excluding them.

A. C. JAMES, *Senior Registrar in Child and Adolescent*
Psychiatry, Maudsley Hospital, London

Roots and Shoots: A Guide to Counselling and Psychotherapy. By R. F. HURDING. Hodder & Stoughton, London. 1986. Pp. 464.

The author traces the rise of secular psychologies and examines Christian responses to them. The first half of the book examines in some detail the psychological theories from which and on which the practical counselling and psychotherapy is based. It does so in some detail ranging from Behaviourism, through the analytical schools, to the New Therapies. It is well documented and gives the reader an overall view of the broad spectrum covered by the generic concept of "psychology".

In the second half, the author faces the awesome task of presenting the Christian reaction and response. On the whole this might better be described as the Christian Biblical response. The problem which he faces can be seen if we were to turn the process round and give a treatise on the variety of Christian denominations and then give the psychological response to each.

The inherent danger in such a work is that it may appear to conclude that only a Christian can be a therapist or benefit from therapy. While some of the Christian responses might be taken in this light I would perfer to consider the relationship in two ways. Psychology has to presume a philosophy, which may well be Biblical, and the quality of the therapist may well spring from his or her spiritual strength.

This book provides an important source of understanding both for the Christian of psychotherapeutic theory and for the psychotherapist of the Christian response.

LOUIS MARTEAU, *The Dympna Centre, London*

Child Development and Psychopathology. By DONNA M. GELFAND and LIZETTE PETERSON. London: Sage Publications. 1985. Pp. 156. £19.75 (pb).

This book, the first of a series devoted to developmental clinical psychology and psychiatry, reads more as a collection of five essays than as a coherent account of the relationship between child development and psychopathology. The use, or abuse, of the English language throughout the book was also irritating. Phrases such as "the relationship between developmental and clinical child psychology as a well known 'smouldering civil war', in which those who are naturally close to each other have engaged in combat" and "Fortunately, ideological strife is not ubiquitous" reminded me more of Rambo than of Piaget. There is little recognition that empirical research has significantly altered views about child development. I cannot recommend this book.

D. P. HOARE, *Senior Lecturer in Child and Adolescent Psychiatry, University of Edinburgh, Royal Hospital for Sick Children, Edinburgh*

Animal Models for Psychiatry. By J. D. KEEHN. London: Routledge & Kegan Paul. 1985. Pp. 251. £20.00.

Professor Keehn draws on case material and experimentation to illustrate some of the ways in which animal models can have psychiatric value. Early chapters discuss the status of animals and describe many examples of abnormal animal behaviour. Particularly welcome in a work ultimately concerned with the alleviation of suffering is a chapter devoted to the welfare of animals and the ethics of research. However, an initial section clarifying basic concepts (definitions of abnormality, models in psychology, reductionism) would have been helpful to newcomers to the subject. Later chapters describe attempts to increase our understanding of human abnormal behaviour by the use of animal models. The topics covered include neuroses, substance abuse, psychotic behaviour, and depression. Many of the models discussed are from the "Skinnerian" school of experimental psychology and from ethology.

The strength of this book is that it sets out some of the contributions of animal models in an interesting and positive way. Its weakness is a lack of critical appraisal. The usefulness of animal models is more frequently asserted than justified; and the models are not convincingly assessed in the context of alternatives. The claim in the concluding chapter that "Animal models may be all that we have for finding new ways to treat the mentally ill" (p. 207) requires more justification than this book provides, and would, I am sure, be firmly disputed by many practitioners working with cognitive and humanistic approaches.

GLYN V. THOMAS, *Lecturer in Psychology, University of Birmingham*

Social Work, Psychiatry and the Law. By NORMAN N. PRINGLE and PAUL J. THOMPSON. London: William Heinemann Medical Books. 1986. Pp. 241. £8.95.

The authors have tried to bring together an outline of psychiatry, social work and the current law relating to the mentally disordered. Part I gives a superficial account of the main psychiatric disorders (including the disturbances of childhood and adolescence). Psychopathic disorder is inadequately dealt with and the M. H. Act definition is given twice. Morbid jealousy is dealt with in the section dealing with aggressive psychopathy. Mental Impairment is dealt with in 4 pages, and the chapter on Methods of Treatments is a curious assemblage of poorly connected facts. Part II is concerned with the social work practice and legislation. The sections on the role of the A.S.W. in assessment are quite helpful but the authors' appraisal of the law is patchy. The wrong date is given for the 1890 Lunacy Act; Section 117 of the 1983 Act is concerned with the after-care of patients *who have been detained*; the fact that the Code of Practice is a *Draft* is not made clear and the authors imply that it has been promulgated by the MHAC whereas it is in fact a DHSS document. The very brief material dealing with admissions from the courts could mislead the ill-informed, and the references to further reading at the end of each chapter are not clearly related to the matters discussed in the text. As a representative of social work I am distressed that I cannot give this social work contribution a positive recommendation.

HERSCHEL PRINS, *Former Director, School of Social Work, University of Leicester*

Brain Neurotransmitters and Psychiatry. By A. VILLENEUVE. Obtainable free of charge from Astra Pharmaceuticals Canada Ltd, 1004 Middlegate Road Mississuaga, Ontario, Canada L4Y 1M4. 1985. Pp. 108.

This book is a small treatise in which distinguished research workers, mainly from Canada, but also from France and the United States, contribute a series of articles bearing strictly on neurotransmission and its relationship to events both inside and outside the brain. The short crisp chapters include the "Effects of Hormones on Brain Neurotransmitters", "Behavioural Approaches of the Biochemical Mechanism of Action of Psychoactive Drugs", "Indolamines in Affective Disorder and Suicide", and "Psychiatric Aspects of Neuroendocrine Disorders". Dopamine and dopaminergic systems, norepinephrine, neuromodulators, and the role of neurotransmitters in anxiety are carefully considered. Sources are fully documented throughout, but there is no general index. This slender volume is easy to read, and moderately easy to understand. It should be particularly useful for junior staff already familiar with basic neuroendocrine physiology and biochemistry.

JOHN POLLITT, *Medical Director, Hayes Grove Priory Hospital, Kent*

Marital Therapy in Britain. Edited by WINDY DRYDEN. **Vol. 1. Context and Therapeutic Approaches.** Pp. 349. $8.50. **Vol. 2. Special Areas.** Pp. 350. £8.50. London: Harper & Row. 1985.

I cannot say that I can strongly recommend either of these volumes. There are some excellent chapters, particularly those of Treacher and Street, who are recognised teachers and practitioners of family therapy. The latter includes a quite proper discussion on the relevance of marital therapy, particularly when there are children. I believe Street agrees with me in suggesting that such a course of therapy would be irrelevant and that family therapy would be the treatment of choice. This, of course, does not apply where there are clear and discrete sexual difficulties and there are a number of good chapters addressing this particular aspect of therapy, which included a stimulating and controversial chapter by Martin Cole on the use of surrogate therapists, which leaves many questions tantalisingly unanswered. The Institute of Marital Studies have contributed excellently to this book and maintain the high standard of their publication since their inception. The section on research inevitably leans heavily on sources outside Britain since, with the exception of Michael Crowe, there is not much to write about within the United Kingdom.

JUSTIN SCHLICHT, *Consultant Psychotherapist, The Maudsley Hospital, London*

The Death of Desire. A Study in Psychopathology. M. GUY THOMPSON. New York: New York University Press. 1985. Pp. 215. $35.00.

The author attempts to bridge the gap between phenomenology and psychoanalysis. Phenomenologists do not accept Freud's concept of the unconscious. They are concerned with "appearances", and "for Freud, the unconscious *does* appear – as 'desire' ". This desire is not Freud's libido. Thompson defines it (with Hegel) in terms of the subject's existential appeal for recognition by another one, rooted in "a lack at the heart of being".

The "death of desire" is its elimination by denial or the illusion of fulfillment. For Thompson, all psychopathology springs from that death. The "murderer" is the ego, here not seen as the carrier of identity but (echoing Lacan) as the sum of identifications, and the seat of all resistance to therapy. Neurotic and psychotic symptoms are in the service of the flight from the pain of unfulfilled desire. It is the therapist's task to help the patient to face this pain. Therefore, the therapist needs to avoid collusion with the patient's ego.

There is an important chapter on the place of time in psychopathology and treatment, influenced by Heidegger's concept of temporality. There is an interesting redefinition of perversion as *any* sexual activity that does not "desire" the recognition of a partner, so that also "normal" heterosexual acts could at times be called perverse. A concluding chapter surveys the role of language in psychoanalysis.

The book is lucidly written but not easy to read, as it raises very complex issues. I recommend it warmly to anyone interested in the philosophical aspects of psychoanalysis.

H. COHN, *Psychologist, Fabye House, Kew, Surrey*

Behavioural Case Formulation. Edited by IRA DANIEL TURKAT. New York: Plenum Press. 1985. Pp. 321. $35.00.

The uncompromising objective of this book is to guide its behaviourally-trained reader to formulate complex clinical cases. After a basic introduction to behavioural interviewing and formulation by Wolpe and Turkat, the format adopted is that of illustrative chapters. Each begins with a clinical case summary followed by discussion of the condition described in relation to DSM III or psychiatric practice, then from a psychometric or behavioural perspective. The case vignette is then re-examined and formulated in behavioural terms.

Malatesta's excellent chapter on Geriatric Organic Syndromes alone fulfils the aims of the book. For the rest, the chapters on Paranoid Personality Disorder, Antisocial Personality Disorder and Histrionic Personality serve better as demonstrations of the limitations of a strictly behavioural approach to complex problems. The absence of behavioural techniques to follow on from the often laboriously derived formulations is frankly admitted at the end of the chapter on Alcohol Abuse and implied by the absence of treatment outcome in the other cases discussed. One's mounting incredulity is compounded by the acknowledged dearth of a relevant research literature.

Only tutors of trainee clinical psychologists may be tempted to order this book, as an object lesson on the hazards of too narrow a conceptual base.

CHARLES LUND, *Consultant Psychotherapist, Royal Victoria Infirmary, Newcastle upon Tyne*

Tics and Related Disorders. By A. J. LEES. Edinburgh: Churchill Livingstone. 1985. Pp. 276. £30.00.

A comprehensive account of the idiopathic tic is followed by a description of the more exotic Gilles de la Tourette syndrome, the essential features of which are multiple body and vocal tics beginning in childhood or adolescence. Coprolalia is commonly associated. Haloperidol, and other neuroleptics such as pimozide, produce marked improvements in 75% of patients. Also of interest to psychiatrists is the uncommon but distressing Meige Syndrome characterised by blepharospasm, grimacing, and oromandibular torsion. When idiopathic, this is often associated with manic-depressive psychosis, but it can occur as a potentially irreversible complication of neuroleptic treatment. There is a useful chapter on the drug-induced dyskinesias, although the relationship of these to tics is not very clear. This readable and well-presented book should find a place in most psychiatric libraries.

D. J. S. FERNANDO, *Clinical Assistant in Psychiatry, Glenside Hospital, Bristol*

Misuse of Drugs. By PATRICK BUCKNELL and HAMID GHODSE. London: Waterlow Publishers. 1986. Pp. 410. £35.00.

This book is the second in a series of volumes, each of which deals with a specialised aspect of the criminal law.

The authors are a practising barrister and a psychiatrist; their primary readership is the legal profession, rather than psychiatrists or other health care professionals. In keeping with this aim, the bulk of the book is devoted to legal matters and the law. The sections on the nature of drug addiction, drugs of dependence and the treatment of drug dependence are comparatively brief and deal with issues at a level appropriate for ensuring that lawyers are informed about this topic, but which is at the same time insufficiently detailed for persons directly concerned with the study and management of drug dependence.

If psychiatrists buy this book, therefore, it will be because of its legal content. For anyone who requires an authoritative exposition of the law relating to drug misuse, together with many of the relevant statutes themselves (reprinted as appendices, which constitute more than half of the book), this is an essential book.

There is a useful directory of national and regional organisations and clinics concerned with drug dependence.

PAUL WILLIAMS, *Senior Lecturer, Institute of Psychiatry, London*

An Introduction to the Psychotherapies (2nd edition). Edited by SIDNEY BLOCH. Oxford: Oxford University Press. 1986. Pp. 285. £8.95 (pb), £15.00 (hb).

The first edition of this introduction had a releasing effect on students who had previously found themselves dazed by the subject's complexity. It distinguished in simple and unambiguous language the essential differences of major forms of psychotherapy, and by its unifying title established the term 'the psychotherapies' in general nomenclature. Two new chapters have been added to the second edition. The first, by Rosen, on brief focal psychotherapy shows skilful handling of an important field and is a model of pithiness and clarity. Wolff, on client centred psychotherapy, surveys the field whilst focusing primarily on the individual treatment of children by dynamic and non-directive psychotherapies. Both chapters follow the format of earlier contributions, commenting on the goals, theory and techniques of therapy as well as on the training needed. Essential references are quoted together with recommended reading. This book is a "best buy".

BRIAN LAKE, *Consultant Psychotherapist, St James University Hospital, Leeds*

Neurotransmitter Actions on the Vertebrate Nervous System. Edited by MICHAEL A. ROGAWSKI and JEFFERY L. BARKER. New York: Plenum. 1985. Pp. 511. $69.50.

Neurotransmission is at the heart of many disciplines and is particularly relevant for neurochemists and psychopharmacologists. This book is a valuable source of information for all aspects of neurotransmission in vertebrates, and includes sections on amino acids, acetylcholine, biogenic amines, neuropeptides, adenosine and ATP. Although the multi-authored text leads to inevitable repetition, the chapters by the editors on GABA and noradrenaline are models of clarity and well worth reading by research workers in biological psychiatry.

PETER TYRER, *Consultant Psychiatrist, Mapperley Hospital, Nottingham*

Human Relationships: An Introduction to Social Psychology. By STEVE DUCK. London: Sage Publications. 1986. £5.95 (pb), £17.50 (hb).

Many mental health professionals experience difficulty in understanding adequately the relevance of the 'frontier' discipline of social psychology to their day-to-day practice. This short book is intended primarily for undergraduates. Duck's central concern is with relationships, which 'run through the fabric of our lives ... but are regarded as too important or too obvious to write about ...' His chosen topics include Social Emotions, Communication Skills, Long-Term Relationships, and aspects of relationships with families, friends, acquaintances and strangers. The chapter on socio-psychological aspects of health is the most valuable and there is an interesting survey on stressors in relation to psychosomatic disorders. The author's style is easy and refreshingly humorous. This book should be useful for those coming to psychiatry with little knowledge of psychology; they will find that this is psychology with a 'human face'.

HERSCHEL PRINS, *Former Director, School of Social Work, University of Leicester*

My Self, My Many Selves. By J. W. T. REDFEARN. Orlando: Academic Press. 1986. Pp. 142. $40.00 (hb), £24.00 (pb).

This book, by one of the most experienced British Jungian Analysts, is an account of the notion of self in Jungian psychology. This is a highly complex and subtle concept, difficult to grasp especially in the precise language of academia. This Redfearn has happily eschewed. In its place he has adumbrated the self, or more aptly the selves, experientially, almost poetically, drawing on his own experiences and feelings and those of his analysands. I must say that I found this an illuminating and sensitive description, which anyone concerned with psychotherapy should find valuable to read.

Redfearn's thesis is that "... we are not one person but many, although some people are more one person than others. Our feeling of "I", as well as our behaviour, is being competed for and dominated by our various selves, one of which is in charge at one time, another at another." What is good about this book is that although distinctively and authoratively Jungian, Redfearn is not dogmatic. He admits that these phenomena, of archetype and complex, can be encapsulated in orthodox Freudian and object-relation theory. It is this concentration of the phenomena of selves and how they may be best understood that makes the book of interest to a wider readership than Jungians.

This beautifully produced volume can be warmly recommended.

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

Published by authority of
The Royal College of Psychiatrist

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al*, *British Medical Journal*, 7 May 1983, **286**, 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins,** and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and th reference list are in complete agreement as regards dates an spelling of names. The text reference should be in the for '(Smith, 1971)' or 'Smith (1971) showed that . . . '

DURKHEIM, E. (1897) Le Suicide. Paris. Translate (1952) as Suicide: A Study in Sociology, by J. A Spaulding & C. Simpson. London: Routledge & Kega Paul.

KENDELL, R. E. (1974) The stability of psychiatr diagnoses. British Journal of Psychiatry, **124**, 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970 Education, Health and Behaviour. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosi and treatment. In Pathology and Treatment of Sexua Deviation (ed. I. Rosen) Oxford: Oxford Universit Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols an Abbreviations: A Guide for Biological and Medical Editor and Authors* (3rd ed. 1977), £2.00, available from th Publications Office of the Royal Society of Medicine. Term or abbreviations which might not be understood by th average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separat sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or othe camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

Psychiatrists

$66,400–$77,000 (Classified)
$84,200–$103,400 (Contract)

Plus patient care allowance of $4,100 per year

Plus $40,000 income-tax free underserviced area grant available, paid quarterly over 4 years

This is an opportunity with the MINISTRY OF HEALTH, Lakehead Psychiatric Hospital, an accredited psychiatric facility, with over 500 employees and a rated bed capacity of 237, serving the population of Northwestern Ontario. This is a teaching hospital affiliated with the University of Western Ontario, providing progressive psychiatric services through its crisis, active treatment, outpatients, substance abuse, rehabilitation and psychogeriatric units. You will work with multidisciplinary teams in providing active treatment programs on the acute admission unit, together with consultative services to other units within the hospital; participate in training programs for medical students; help provide inservice education and community consultation.

Location: Thunder Bay. Thunder Bay is a city of 125,000 with excellent educational programs, elementary, secondary and postsecondary level. Uncrowded recreational opportunities exist throughout the year, and a well-developed transportation system provides frequent services with Southern Ontario, Minnesota and Manitoba.

Qualifications: Specialty certificate in psychiatry from the Royal College of Physicians and Surgeons of Canada and licenced or eligible for licensure by the Ontario College of Physicians and Surgeons.

Please send application/resume, quoting file HL-24-52/86, as soon as possible to Dr. J. B. Frost, Medical Director, Lakehead Psychiatric Hospital, 580 Algoma Street North, P.O. Box 2930, Thunder Bay, Ontario, Canada P7B 5G4.

Equality of Opportunity for Employment

Ontario Public Service

M.Sc. IN FAMILY THERAPY

combining an

ADVANCED TRAINING IN FAMILY THERAPY

at

THE TAVISTOCK CLINIC

and an M.Sc. awarded by

BRUNEL UNIVERSITY 1987/88

Applications are invited for a multi-disciplinary clinical training in family therapy for experienced clinicians who wish to develop their practice and teaching of family therapy.

A two year, two day per week programme will include clinical work with families in the Child and Family Department, with group supervision using video tapes and one way mirror observation, together with theoretical and experimental seminars in various integrative approaches. Specialised clinical experience in services involving child sexual abuse, drug abuse and liaison with schools are available.

There will be opportunities for supervision in teaching practice and developments of research projects.

Upon successful completion of required academic work including a dissertation, an M.Sc. will be awarded by Brunel University.

Applications will be considered from those who do not wish to register for an M.Sc.

Closing date: **6th April 1987**

Further information and application forms available from:

The Training Administrator, The Tavistock Clinic, 120 Belsize Lane, London, NW3 5BA.

Tel: 01-435-7111, Ext: 313 or 469.

A general prospectus of training is available upon request.

THE TAVISTOCK CLINIC

The TAVISTOCK CLINIC'S Celebration of DR BOWLBY'S 80th BIRTHDAY will include an International Conference in London — "FRUITS OF ATTACHMENT THEORY: FINDINGS AND APPLICATIONS ACROSS THE LIFE CYCLE" — on 26th and 27th June 1987.

An International group of distinguished workers who have contributed to Attachment Theory will present recent research findings related to all age groups and will discuss their relevance to practice: speakers include, Ainsworth, Grossmann, Hinde, Main, Marris, Parkes, Radke Yarrow, Raphael, Weiss, and others.

Further details from and applications to:

Attachment Conference Co-ordinator,
Training Office,
Tavistock Clinic,
120 Belsize Lane,
London, NW3 5BA.
England.

THE UNIVERSITY OF NEWCASTLE
New South Wales, Australia

PROFESSOR OF PSYCHIATRY
Faculty of Medicine — (Position No. A157/86)

Applications are invited from suitably qualified medical graduates for appointment to the tenured Chair of Psychiatry in the Faculty of Medicine.

The Faculty enrolled its first students in 1978 and seeks to educate thoughtful and caring graduates, clinically competent, sensitive and capable with respect to community and psycho-social issues. Its educational programme is community-oriented and based upon problem solving in small group tutorials. There is close integration between disciplines.

The Discipline of Psychiatry has already made a major contribution to the development of psychiatric services in the Hunter Valley region, to postgraduate training and to the development of other relevant service programmes.

An academic unit has been established at the Newcastle Mater Misericordiæ Hospital and liaison services and child psychiatry services will be developed at the new teaching hospital, to be opened in 1991.

The Faculty seems to continue an orientation to preventive care in the community, and community-based research.

The Discipline currently consists of the chair, a senior lectureship in adolescent psychiatry, a lectureship/senior lectureship (vacant pending appointment to the chair) and a professional officer. It is supported by a substantial number of clinicians in public and private practice. It has an active research programme into adolescent, alcohol and puerperal psychiatric epidemiology, as well as recognised interest in linguistic and cognitive abnormalities in schizophrenia.

The appointee will be appointed as Adviser in Psychiatry to the Regional Director of the Department of Health and will be expected to work closely with the Regional Director of Psychiatry Services.

The salary for a professor is $A58,348 per annum, plus a clinical loading of up to $A10,433 per annum. Members of the academic staff enjoy a limited right of consultative practice. The New South Wales government has recently approved an additional allowance for clinicians who participate in an on-call roster.

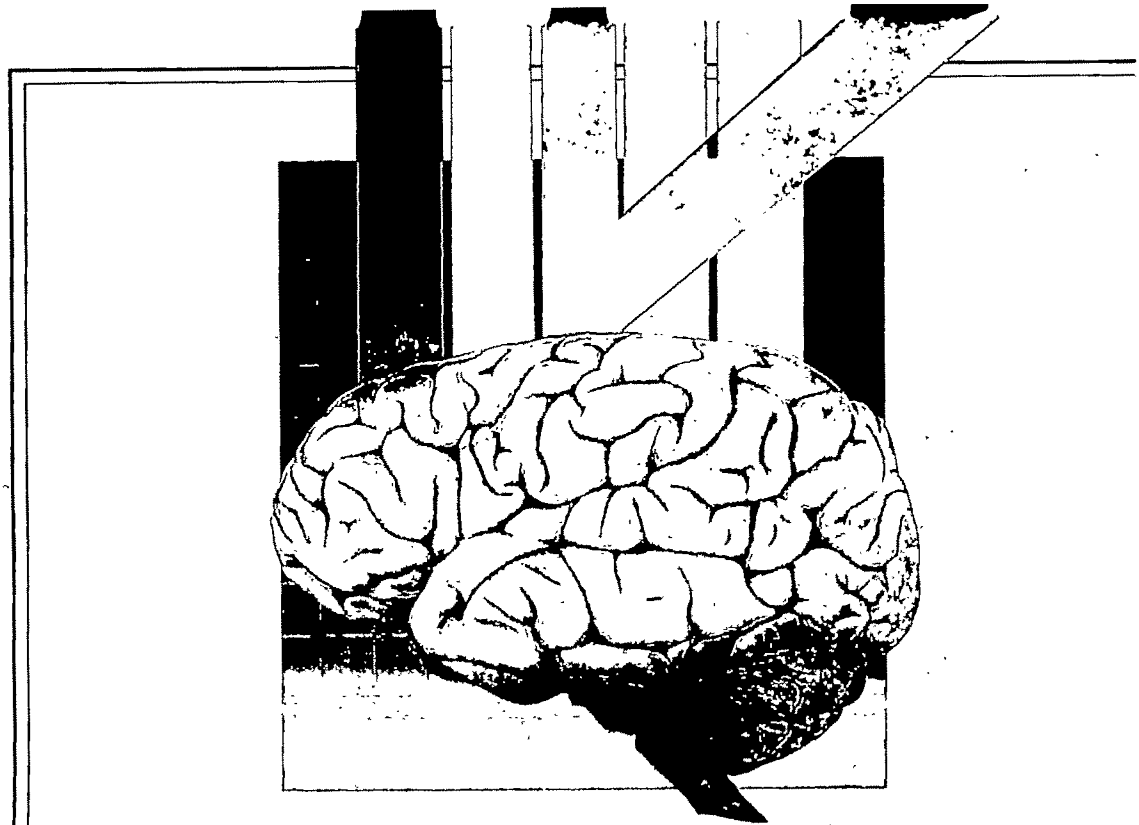
The University reserves the right to fill the post by invitation.

Further details about this position, the Medical School or its affiliated hospitals, may be obtained from the Dean, Professor J. D. Hamilton, University of Newcastle, NSW 2308, Australia, who would welcome enquiries.

Conditions of employment, including method of application and other particulars, may be obtained from the Secretary General, Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF.

Applications close **27 February 1987.**

Equality of employment opportunity is University policy



The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine[1] trifluoperazine[2] and haloperidol[3] but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia[4]

Lecture

Assessment of Suicide Risk[1]

K. HAWTON

Among the many clinical skills that psychiatrists must acquire, the ability to assess the risk of patients killing themselves is probably the most important and demanding. It is often a crucial factor when making clinical decisions, such as in the choice of treatments, when deciding whether admission to a psychiatric hospital is necessary and when implementing the Mental Health Act. This review first explores the problems in assessing suicide risk. Subsequently, the risks of suicide for patients with major psychiatric disorders and for particular clinical populations, including hospitalised patients and suicide attempters, are examined together with the findings from research investigations which can assist psychiatrists when making decisions about the risk of suicide.

Problems in assessing suicide risk

The psychiatrist's task in assessing suicide risk is confounded by serious theoretical and practical difficulties.

Base-rate problem

The main difficulty is that of predicting what is fortunately a relatively rare event, especially as the available criteria are necessarily crude. This is illustrated by the fact that if one examines a high risk group, such as suicide attempters, and makes the assumption that the risk of suicide during the year after an attempt is of the order of 1% (see below), among 1000 suicide attempters there may be ten deaths by suicide during the following year. If our ability to predict those who will kill themselves is 80% efficient (this is as good a figure as is claimed by most workers), we should be able to identify correctly eight out of ten of the eventual suicides. However, in doing so a further 192 individuals are likely to be identified incorrectly as possible suicides. This rate of false-positive prediction is far too great if, for example, a decision were made to concentrate therapeutic efforts on only those most at risk.

Difficulties in applying general risk factors to individuals

While suicide risk factors may be useful in identifying high risk *groups* of individuals, such criteria are far less useful when it comes to predicting risk in the *individual* patient. To illustrate this in an extreme fashion, while both sex and age may be of some assistance in predicting suicide risk in a group of people, such criteria are of only limited value when considering an individual. Even when large numbers of criteria are employed, including some which are far better predictors than age and sex, this problem still pertains.

Means of identifying risk factors

Our knowledge of risk factors for suicide is based largely on the findings of studies that have examined the distinguishing characteristics of those people who, out of a group of individuals, kill themselves during a fixed time period, irrespective of what treatment may have been provided. However, some additional suicides are likely to have been prevented by the use of appropriate and effective treatment. Therefore, such studies actually identify factors which predict the risk of suicide *in spite of* treatment, and thus there must be some doubt about the extent to which the findings assist the psychiatrist in everyday clinical practice.

Short-term vs long-term risk

A major concern in clinical work is usually the assessment of whether or not a patient is likely to commit suicide during the next few hours, days or weeks, yet most of our knowledge concerning risk factors for suicide is based on examining the risk in the long term (and indeed this will be the main focus of this review). However, long-term risk factors are unlikely to be *identical* to those that predict short-term risk. Again, therefore, doubts exist concerning the extent to which findings from long-term follow-up studies can be used to assist the clinician in the assessment of short-term risk.

---

[1] Based on a lecture presented in the Maudsley Bequest series to The Royal College of Psychiatrists' Winter Quarterly Meeting on 6 February 1985.

Changeability of risk factors

A further problem with long-term risk factors is that we cannot predict what events or changes an individual will face in future which might alter his or her risk status. For example, a happily married man with a good job might, in a couple of years time, have become divorced, unemployed and have started drinking heavily. Thus he will have moved from being a member of a low risk group to one of much higher risk. Ideally, risk factors used for predictive purposes should be stable, but clearly most are not. Therefore, as Kreitman (1982) has noted, long-term prediction of suicide risk on the basis of current characteristics may be a somewhat illogical exercise.

Risk factors are not universal

It is important to acknowledge that the risk factors for suicide differ according to the group of individuals under consideration. For example, there are important differences between risk factors in psychiatric hospital in-patients and those identified for suicide attempters.

These problems should be borne in mind in assessing the value of research findings concerning suicide risk in various clinical disorders and populations. Before considering specific psychiatric disorders, there are a few general factors relevant to suicide risk, whether or not a person is suffering from mental illness. First, suicide is more common in men than women. Secondly, the risk increases with age until late middle or early old age, although recently there has been an increase in suicide rates among young men (McClure, 1984). Thirdly, most people who kill themselves have recently told, or intimated to others, what they were thinking of doing. Such communication may be straightforwardly direct, or it may be more subtle (Robins *et al*, 1959*a*).

Suicide risk and psychiatric disorder

The prevalence of various psychiatric disorders, based largely on retrospective diagnoses, among individuals in three major studies of suicides is summarised in Table I. In all three studies, the suicides were consecutive series identified through local coroners. The methods used in each study were similar, and included interviews with relatives and other informants, as well as scrutiny of official documents. However, since the studies included only cases in which an official verdict of suicide had been reached, and not probable suicides without an official suicide verdict, the findings may not be entirely representative of *all* people who kill themselves. For example, a verdict of suicide might be more likely in someone with a known psychiatric history, which might result in an overestimate of the prevalence of psychiatric disorder among suicides. Furthermore, the reports of informants could have been biased, with a tendency to over-report psychiatric symptoms in an attempt to explain or justify the act.

The disorders indicated in the table were the major or primary diagnoses—in many cases more than one diagnosis was made. Although amalgamating the findings from the three studies is scientifically unsound, particularly in view of the different diagnostic procedures that were employed, it provides an overall impression of the extent to which people who kill themselves are likely to suffer from various psychiatric conditions.

TABLE I
Psychiatric disorders among completed suicides (%)

	Affective disorders	*Alcoholism*	*Schizophrenia*	*Other psychiatric disorders*	*Total with psychiatric disorders*
Robins *et al* (1959*a*) ($n = 134$)	47	25	2	20	94
Dorpat & Ripley (1960) ($n = 108$)	30	27	12	31	100
Barraclough *et al* (1974) ($n = 100$)	70	15	3	5	93
($n = 342$)	48	23	6	19	96

The first conclusion to be drawn from these studies is that virtually all of the individuals who killed themselves were thought to have suffered from psychiatric disorders. Secondly, approximately half had affective disorders, almost a quarter alcoholism and approximately 5% schizophrenia. Factors that can assist in the assessment of suicide risk in these three disorders are discussed below, together with some comments on the risk of suicide in individuals with neuroses and those with major personality disorders.

Affective disorders

On the basis of 17 follow-up studies of patients with affective disorders, Guze & Robins (1970) calculated that approximately 15% ended their lives by suicide, which is 30 times the risk in the general population. They also noted that the risk of suicide is highest relatively early in the course of the disorder and that, unsurprisingly, suicides usually occur during episodes of depression rather than during remission. However, since depression is the most common condition for which patients are referred to psychiatrists, and a minority appear to be at risk of suicide, considerable efforts have been made to identify the characteristics of those patients most at risk.

Barraclough & Pallis (1975) compared 64 suicides diagnosed retrospectively as having depression with 128 living depressed individuals. The following characteristics were more common among the suicides: male sex, older age (in females), single status, living alone (six times more frequent than in controls) and having a history of suicide attempts (seven times more frequent). Symptoms which distinguished the suicides were insomnia, impaired memory and self-neglect. Furthermore, almost half the suicide showed retardation, and although this did not distinguish them significantly from the controls, this finding questions the dictum that retardation protects depressed patients against suicide. Depressed patients with delusions may be at greater risk than similar patients without delusions (Roose *et al*, 1983). A study by Roy (1983) of 21 depressed suicides and 21 depressed controls, matched for sex and age, confirmed that suicides are more likely to be single, living alone and have a history of previous suicidal behaviour.

Hopelessness, or negative expectations about the future, has long been emphasized as one of the most important factors leading to suicide in depressed individuals. Beck proposed that hopelessness might be the main symptom preceding suicide and could be of greater importance than depression itself (Beck *et al*, 1975*b*). He and his colleagues have recently examined the predictive value, in terms of suicide risk, of hopelessness, depression and suicidal ideation in 207 patients admitted to psychiatric hospital in-patient care with suicidal ideas, but not a recent suicide attempt (Beck *et al*, 1985). Measures of depression (Beck Depression Inventory [Beck *et al*, 1961]), hopelessness (Hopelessness Scale [Beck *et al*, 1974*b*]) and suicidal ideation (Scale for Suicidal Ideation [Beck *et al*, 1979]), all of which were completed during the 72 h following hospital admission, were compared between the 14 patients who ended their lives by suicide during the 5–10 years follow-up and those who were alive at the end of the follow-up period. While the suicides did not differ significantly from the survivors in terms of the original levels of depression and suicidal ideation, they did differ in terms of their scores on the measure of hopelessness, individuals who died by suicide having described themselves are more pessimistic about the future than those who had survived. Further support for this finding was provided by the fact that the pessimism item within the depression scale also correlated with risk of suicide. The results of this study have been replicated in a large group of psychiatric out-patients (Herold *et al*, in preparation).

Beck has elaborated on his view of hopelessness and depression in relation to suicide risk, saying that a sense of hopelessness in depression may arise out of activation of particular underlying cognitive patterns (probably established in response to early experiences), and that people differ in the extent to which they are prone to developing pessimistic attitudes towards the future, even when suffering from similar degrees of depression (Beck *et al*, 1985). Thus a high degree of hopelessness during one episode of depression may not just increase the current risk of suicide, but may also predict a high degree of hopelessness, and therefore greater risk of suicide, in a subsequent episode. This accords with clinical experience. Beck's work emphasises the care with which one should assess every depressed patient's attitude towards his or her future, as well as enquiring about severity of depression and specific suicidal ideas and plans. Furthermore, in patients thought to be of high risk, special care should be paid to the prevention and early detection and treatment of subsequent episodes of depression.

Alcoholism and other addictions

On the basis of several follow-up studies, Miles (1977) estimated that approximately 15% of alcoholics eventually commit suicide. In contrast to the affective disorders, alcoholic suicides tend to occur relatively late after the development of the disorder (Robins *et al*, 1959*b*).

The majority of alcoholics who kill themselves are also depressed (Pitts & Winokur, 1966; Barraclough *et al*, 1974). Motto (1980) identified three further factors which distinguished alcoholic suicides from surviving alcoholics—poor physical health, poor work record in the previous 4 years and a previous history of suicidal behaviour, especially if this had involved serious suicidal intent. Murphy and colleagues (Murphy & Robins, 1967; Murphy *et al*, 1979) demonstrated that the recent loss of a close relationship through separation or death was especially common among alcoholic as compared with depressed suicides. During the 6 weeks prior to suicide, such an event occurred in 32% of alcoholics compared with only 3% of depressives in their first study, and 26% compared with none in the second. Although there was no comparison group of surviving alcoholics to determine if the frequency of loss was especially high for people with this disorder, intuitively it appears to be so.

The risk of suicide among *drug addicts* is also known to be very high. James (1967) suggested that the risk of suicide among male heroin addicts is approximately 20 times that of the general population. Unfortunately there appears to be a paucity of empirical evidence which can assist in the detection of those drug addicts who are most at risk of suicide. However, the risk factors identified for other populations, especially alcoholics, are likely to be relevant.

Schizophrenia

Because such varying diagnostic criteria have been used for schizophrenia, at least until very recently, the risk of suicide among individuals with schizophrenia is uncertain. Miles (1977) reviewed a series of follow-up studies, most of which would have involved different diagnostic criteria, and estimated that 10% of schizophrenics died by suicide, the risk being particularly high during the early years of the illness.

On the basis of a comparison of 30 chronic schizophrenics who had killed themselves, with 30 surviving chronic schizophrenics, Roy (1982*a*) reported the following distinguishing characteristics of the suicides: male sex, relatively young age, chronic illness marked by relapses and remissions, depression noted at the last contact; expression of suicidal ideas, unemployment, and recent discharge from in-patient psychiatric care. Clearly, these characteristics apply to a large number of schizophrenic patients. A recent study has identified other and more subtle risk factors (Drake *et al*, 1984). One important finding was that all of a series of schizophrenic suicides occurred during a relatively non-psychotic phase of the illness. Furthermore, most of the suicides had attained a relatively high level of educational status prior to the illness, were usually living alone and had previously indicated suicidal intent. They tended to have high, non-delusional expectations of themselves, were largely aware of the effects of their illness and its consequences for their future functioning, and tended to be depressed, particularly with feelings of inadequacy, hopelessness and suicidal ideas, rather than biological features of depression. In keeping with Beck's postulate of a strong association between negative expectations about the future and suicide, three variables were especially important in predicting suicide: namely, fears of mental disintegration, suicide threats and hopelessness. Virtually all of the suicides and very few surviving controls had shown some or all of these symptoms. Akathisia (Drake & Ehrlich, 1985) and abrupt stopping of medication (Cohen *et al*, 1964) may also increase the risk of suicide. These findings emphasise the need for patients with schizophrenia to receive long-term support and also careful surveillance during remission as well as during relapse.

Neuroses

Sims & Prior (1978) demonstrated that patients with a variety of neurotic conditions had an increased risk of suicide. However, since their sample consisted of patients who had all been admitted to psychiatric in-patient care they would have had relatively severe disorders. The risk was especially high during the year after discharge. Many patients had a diagnosis of depressive neurosis. It is unclear what proportion of these might have now received a diagnosis of major depression. However, the suicide risk was high even when patients with depressive neurosis were omitted (Sims, 1984). Coryell has demonstrated that the risk is high in patients with panic disorder (Coryell *et al*, 1982) but not in those with obsessive-compulsive disorders (Coryell, 1981). Unfortunately, further information is lacking about the specific characteristics of patients with neuroses who are at particular risk.

Personality disorders

Little is known about the risk of suicide in people with abnormal personalities, except that they are relatively common among suicides (Barraclough *et al*, 1974), and that as many as 10% of suicides suffer from sociopathic disorders (Ovenstone & Kreitman, 1974). Individuals most at risk are probably those who show marked lability of mood, aggressiveness, impulsivity and those who have become alienated from their peers, especially if this picture is complicated by alcohol or drug abuse.

Other factors relevant to the assessment of suicide

Physical illness

Physical disorders, especially those of a chronic nature, are common among suicides. For example, in Dorpat & Ripley's (1960) study, at least half of the suicides had relatively serious physical disorders and in many cases the illness appeared to have contributed to the suicide. Physical illness was especially common among elderly male suicides. Specific conditions that often occur in suicides include peptic ulcer, cardiovascular disease and malignancies (Sainsbury, 1955; Dorpat & Ripley, 1960). Epilepsy is another important risk factor. In a review of several follow-up studies, Barraclough (1981) estimated that there is a five-fold increased risk of suicide in this condition, and that the risk may be very much higher in people with temporal lobe epilepsy.

Bereavement

Death of a parent during childhood may increase the risk of suicide in adulthood (Dorpat *et al*, 1965), probably because of increased vulnerability to depression (Brown & Harris, 1978). Recent bereavement, particularly loss of a spouse (McMahon & Pugh, 1965) or parent, is also a risk factor. Bunch (1972) found that the risk was increased for at least 4 or 5 years following bereavement, and was particularly high during the first 2 years. Those most at risk had a history of psychiatric disorder and/or suicidal behaviour before the bereavement, and lack of family support following the loss.

Family history of suicide

A family history of suicide appears to increase the risk of suicide in other family members who develop psychiatric disorders (Roy, 1982a,b), although whether this is related to family predisposition to affective disorder and other conditions, to having a family model of suicidal behaviour, or both, is uncertain.

Unemployment

Although there is substantial evidence that the risk of suicide is increased among unemployed men, and to a lesser extent among unemployed women (Platt, 1984), it is unclear to what extent unemployment itself contributes to suicide risk, or whether the association is due to the effects of unemployment on mental health, or whether people with poor mental health are at increased risk of becoming unemployed (Smith, 1985). Thus, while Shepherd & Barraclough (1980) found a markedly increased proportion of unemployed men in a series of suicides compared with matched surviving controls, they argued that the association was most likely to be due to a third factor, namely psychiatric disorder, since psychiatric illness seemed to be responsible for both unemployment and suicide in most cases. However, in some individuals, unemployment may also have exacerbated a pre-existing psychiatric condition and thereby increased the risk of suicide. Nevertheless, unemployment is a risk factor for suicide among individuals with psychiatric disorders (Roy, 1982*a*,*b*), irrespective of the nature of this association.

Biological factors

Several recent studies have suggested that abnormally low cerebral serotonin (5-HT) levels may exist in suicides (Asberg *et al*, 1976; Traskman *et al*, 1981; Stanley & Mann, 1983; van Praag, 1983). Whether this relates directly to suicidal behaviour, aggressiveness or severity of depression (Stanley *et al*, 1982) is unclear. However, if in the future cerebral seretonin activity could be evaluated easily by a blood test, it raises the remote possibility of a biological marker of suicide risk being developed that could be used in conjunction with other risk factors.

Psychiatric hospital patients

In spite of all our therapeutic efforts, suicides are relatively common among patients in psychiatric hospitals (Hawton, 1978). The risk on acute units has been estimated at over 50 times that of the general population (Fernando & Storm, 1984), although the risk among *all* psychiatric hospital patients, taking account of the elderly and long-stay, is considerably lower (Copas & Robin, 1982).

Patients with the highest risk are young or middle-aged males with affective disorders or schizophrenia and young females with affective disorders or personality disorders (Pokorny, 1964; Copas & Robin, 1982), especially if there is a history of previous suicidal behaviour (Fernando & Storm, 1984). Risk appears to be increased during the early stages of recovery from illness, when staff vigilance may have lessened (Sletten *et al*, 1972; Gale *et al*, 1980). Morgan & Priest (1984) have suggested that alienation from others on the ward, including staff, often precedes suicide. Some hospital environments may be conducive to certain forms of suicide, (e.g. a high building [Salmons, 1984] or adjacent railway track [Langley & Bayatti, 1984]). The week following admission to hospital (Copas & Robin, 1982) and the month immediately following discharge are the periods of greatest risk (Pokorny, 1964; Roy, 1982*b*). The risk following discharge may be related to the clinical team being misled by spurious improvement in a patient's condition in hospital while stresses outside hospital remain unresolved (Morgan & Priest, 1984).

Suicide attempters

The risk of suicide during the year following attempted suicide is approximately 1% (Kessell & McCulloch, 1966; Buglass & Horton, 1974; Hawton & Fagg, in preparation), which is about 100 times that of the general population. The risk declines somewhat in subsequent years but continues to remain relatively high until at least 8 years after an attempt (Hawton & Fagg, in preparation).

A considerable amount of research has been devoted to identifying those at particularly high risk within this group. One of the first investigations was carried out by Tuckman & Youngman (1963, 1968). This was based on cases identified by the police rather than through hospital referral alone. They demonstrated that the closer an individual's profile, in terms of demographic and clinical characteristics, approaches that typical of completed suicides, the greater the risk of eventual suicide. They developed a list of risk factors on the basis of two major follow-up studies: (i) age 45 years or more; (ii) male sex; (iii) unemployed or retired; (iv) separated, divorced or widowed; (v) living alone; (vi) poor physical heath; (vii) medical treatment within previous 6 months; (viii) psychiatric disorder, including alcoholism; (ix) violent method used in attempt (e.g. hanging, shooting, jumping or drowning; (x) left a suicide note; and (xi) previous attempts. The more items scored positively on this list for any individual, the greater the risk of eventual suicide. For example, attempters with two to five factors had a suicide rate of 6.8 per 1000 while those with ten or more had a suicide rate of over 60 per 1000. Subsequent studies have confirmed most of these factors as important predictors of risk and have added further items. For example, in two investigations, attempters who subsequently killed themselves had far less often experienced the break-up of the relationship with a partner in the year before the attempt and a major row during the 48 h preceding the attempt than had survivors (Pallis *et al*, 1982; Hawton & Fagg, in preparation), probably reflecting the fact that crises concerning relationships often resolve whereas other more chronic difficulties (e.g. poor physical health) may have a poorer prognosis. Two further factors which merit special attention when assessing suicide risk in this population are the *dangerousness of attempts* and *suicidal intent*.

Dangerousness of attempts

There has been considerable debate about whether anything can be inferred about the risk of subsequent suicide from the medical dangerousness of an attempt. For example, Fox & Weissman (1975) found that, while the medical effects of overdoses were greater than the medical effects of self injuries among suicide attempters, the degree of suicidal intent (i.e. wish to die) was generally lower among self-poisoners than those who deliberately injured themselves. Similarly, in a study of a larger series of attempters in Edinburgh, Rosen (1970) found that medical seriousness of attempts did not correlate with psychiatric seriousness (i.e. suicidal intent). In contrast, Pallis & Barraclough (1977), using retrospective assessments of the potential seriousness of attempts made by people who subsequently killed themselves, showed that the danger of the method used in the attempts was a positive, if somewhat weak, predictor of eventual suicide. Nevertheless, the controversy surrounding this question means that dangerousness alone is not a very useful basis for estimating suicide risk. However, it can be useful if the attempter's knowledge of the danger involved in the attempt is taken into account (Beck *et al*, 1975*a*). Thus, while Beck *et al* found that the correlation between suicidal intent and the medical danger in their overall series of attempters was very low, the correlation was very high when they examined separately the attempters who were able to assess acurately the probable outcome of their attempts if treatment had not been received.

Suicidal intent

This refers to the degree of apparent intention to die that is associated with an attempt. Several scales have been developed for assessing suicidal intent, of which the Suicidal Intent Scale (Beck *et al*, 1974*a*) is the most well known, having proved itself very useful in both research and clinical work. It has two sections: the first includes questions concerning the circumstances of the act, and the second includes questions concerning the subject's report about his/her state of mind at the time of the act. Scores on this scale have been shown to correlate with: (i) scores on the Tuckman and Youngman Scale of suicide risk (Pallis & Sainsbury, 1976); (ii) the medical seriousness of attempts in those aware of the dangers involved (Beck *et al*, 1975*a*); (iii) some aspects of depression, especially hopelessness (Minkoff *et al*, 1973; Wetzel, 1976; Dyer & Kreitman, 1984), which, as discussed earlier, is a predictor of eventual suicide in depressed patients with suicidal ideas; and (iv) risk of eventual suicide (Pierce, 1981). Furthermore, patients who make repeated attempts of increasing severity of suicidal intent appear to be at particular risk of suicide (Pierce, 1984).

In the assessment of suicide risk following an attempt, therefore, it is worthwhile taking into account social, demographic and clinical factors like those highlighted by Tuckman & Youngman, suicidal intent as measured objectively and, but only in those with knowledge about the potential risks, the medical danger involved in the attempt. Pallis and colleagues have developed composite scales for assessing suicide risk which include both an assessment of suicidal intent and of sociodemographic and clinical factors, items in the scale being weighted and cut-off points provided for varying degrees of risk (Pallis *et al*, 1984). However, weighting probably limits the practical usefulness of these measures. In everyday clinical work, psychiatrists are probably best advised to take account of all the factors that have been shown to characterise those at risk of suicide, without necessarily completing specific scales, although the Suicidal Intent Scale is worth using routinely. In addition, patients should be asked about their attitude to the future and whether they think they are likely to repeat the act in the near future. Some patients will deny their true intentions; in such cases the psychiatrist should be alerted to this by other factors (e.g. the dangerousness of the current attempt, the apparent hopelessness of the person's situation). Other factors which should be considered include whether or not active support will be available after the patient leaves hospital, the extent to which the patient will engage in after-care, and the likelihood that such help will be beneficial. Suicide risk is, of course, only one aspect of assessment of suicide attempters. A complete assessment should also take account of all the other problems that this population commonly faces, including, for example, relationship difficulties, family problems, alcoholism and other psychiatric disorders.

This review has summarised some of the more important findings from the substantial body of information that is now available concerning factors which can assist clinicians when assessing suicide risk. Clearly, statistical findings from studies of groups of patients can only help clinicians to a limited extent when considering individual patients. In addition, the special characteristics of each patient and his or her circumstances, including the availability of a suitable method for suicide (e.g. a firearm), always require attention. Nevertheless, it is worthwhile for the clinician to have in mind the information that has been provided by research and to ask himself in each case how closely the characteristics of the individual resemble those of people known to be likely to kill themselves.

While the low base-rate of suicide in even the highest risk groups will always limit the discriminatory power of predictive factors, further research is necessary to extend and refine our knowledge of risk factors. Other questions concerning suicide risk which require attention include, for example, how do suicidal ideas fluctuate during the course of an illness, what therapeutic strategies have an immediate effect on suicidal ideation, and do cognitive therapies diminish the extent of future suicidal behaviour by modifying vulnerability to experiencing hopelessness?

Acknowledgement

I wish to thank Professor M. G. Gelder for his helpful comments on an earlier draft of the manuscript.

Changes in Auditory P3 Event-related Potential in Schizophrenia and Depression

D. H. R. BLACKWOOD, L. J. WHALLEY, J. E. CHRISTIE,
I. M. BLACKBURN, D. M. St CLAIR and A. McINNES

Event-related potentials during a two-tone discrimination task were recorded in 24 schizophrenic patients, 16 depressed patients and 59 control subjects. Recordings were made when patients were medication-free. Fourteen schizophrenic and 13 depressed patients were retested at 1 and 4 weeks after the start of treatment, and 13 schizophrenic patients were also tested between 6 and 24 months after the initial recordings. In the schizophrenic group, the P3 latency was significantly prolonged compared with that in the control and the depressed groups, and remained unchanged both after 4 weeks treatment with therapeutic doses of neuroleptic drugs and at long-term follow-up. In the depressed group, the P3 latency did not differ from that of controls. P3 amplitude by contrast was reduced in both the acutely depressed and schizophrenic groups and following treatment became normal in the depressed group but remained reduced in the schizophrenic group. It is suggested that a prolonged P3 latency and reduced P3 amplitude indicate an impairment of auditory information processing in some patients with schizophrenia which is independent of the presence of acute psychotic symptoms and is not influenced by neuroleptic medication.

Electrophysiological studies employing a variety of perceptual tasks have reported changes in auditory event-related potentials which distinguish schizophrenic subjects from controls. The P3 component is a positive deflection recorded from the vertex approximately 300 m after a stimulus. The amplitude of this wave reflects both the unexpectedness of the signal, and the subject's awareness of the relevance of the signal in carrying out a simple cognitive task. The latency of P3 is a measure of the stimulus evaluation time (Kutas *et al*, 1977; Squires *et al*, 1977; Ford *et al*, 1979). A consistently reported observation in schizophrenic subjects is a reduction in the amplitude of P3 with auditory stimuli (Roth & Cannon, 1972; Levit *et al*, 1973. Verleger & Cohen, 1978; Roth *et al*, 1980; Steinhauer & Zubin, 1982; Baribeau-Braun *et al*, 1983; Pfefferbaum *et al*, 1984) and visual stimuli (Pass *et al*, 1980; Brecher & Begleiter, 1983). These changes are unlikely to be secondary to peripheral or brainstem changes (Pfefferbaum *et al*, 1980). Earlier studies have reported no change in P3 latency in schizophrenia, but Pfefferbaum *et al* (1984) have recently reported that in a group of 20 schizophrenic patients the P3 latency was significantly longer than in a group of 115 control subjects.

Changes in the amplitude and latency of other components of auditory event-related potential have also been reported in schizophrenia. N1, a negative wave in the range 90–150 ms post-stimulus, and P2, a positive deflection at 160–220 ms post-stimulus, are generally regarded as reflecting changes in selective attention (Hillyard & Kutas, 1983). Roth & Cannon (1972) found a shorter P2 latency and reduced amplitude which correlated negatively with medication dose in a group of 21 schizophrenic patients. In a group of 20 schizophrenics, Baribeau-Braun *et al* (1983) found N1 amplitude to be larger in patients on small doses of medication compared with those on higher doses. In contrast, Levit *et al* (1973) and Steinhauer & Zubin (1982) found no changes in the amplitudes of N1 and P2 and no correlation between amplitudes and medication dosage. Finally, Pfefferbaum *et al* (1984) reported a reduced amplitude of N1 but not P2 and a shorter P2 latency in patients with schizophrenia.

Changes in amplitude and latency of auditory event-related potentials are not specific for schizophrenia. P3 amplitude is reduced in patients with depression (Levit *et al*, 1973; Roth *et al*, 1981; Pfefferbaum *et al*, 1984). Shagass *et al* (1977, 1978) measured event-related potential following auditory, visual and somatosensory stimuli in 102 medication-free psychotic patients and 28 controls. In the three sensory modalities, the amplitudes of late components of evoked responses were reduced in both schizophrenic and depressed psychotic patients and were normal in non-psychotic patients regardless of diagnosis. The conclusion was that changes in N1 and P2 components reflected an impairment of attention related to psychosis in general and was not peculiar to schizophrenic patients.

Several factors may be responsible for the differing reports of changes in event-related potentials in schizophrenic patients, and these include variation in patient selection, states of medication and differing stimulus paradigms. This present study was designed to measure changes in auditory event-related potentials in patients with acute schizophrenia or depressive psychosis, and to see whether these changes disappeared or persisted with clinical improvement and response to treatment. Changes due to attentional difficulties in acute psychosis could thus be separated from changes reflecting more permanent underlying abnormalities in schizophrenia or depression.

Method

The study included 24 patients admitted to the Royal Edinburgh Hospital who fulfilled research diagnostic criteria (Spitzer *et al*, 1978) for schizophrenia and 16 patients who fulfilled the criteria for major depressive disorder. All patients were interviewed using the Present State Examination (Wing *et al*, 1974) and clinical ratings including the Hamilton Depression Score (HDS) (Hamilton, 1960) and the Brief Psychiatric Rating Scale (BPRS) (Overall & Gorham, 1962) were completed on each day that auditory-evoked responses were recorded. A diagnosis was reached independently by at least two psychiatrists using information from case notes in addition to the diagnostic interview. The signed consent of the patient and their nearest relative for the study was obtained in all cases.

Patients had received no antidepressant drugs or oral major tranquillisers for at least 3 months before initial testing, and no depot neuroleptic drugs for at least 1 year, with the exception of two patients with schizophrenia who had each received intramuscular neuroleptic medication (flupenthixol 20 mg) 6 weeks previously and one patient 3 months before testing. Five schizophrenic and four depressed patients requiring sedation were treated with amylobarbitone sodium (60–200 mg) within 3 days and not less than 10 h before testing. In 14 of the 24 patients with schizophrenia, event-related potentials were recorded before treatment and at 1 and 4 weeks after treatment. These patients were treated as follows: chlorpromazine (6), chlorpromazine and flupenthixol (4), haloperidol (1), fluphenazine decanoate (1), haloperidol and flupenthixol (1), trifluoperazine hydrochloride (1).

Thirteen patients with schizophrenia consented to be retested between 6 and 24 months (mean 13 months) after their initial assessment. Eleven patients could not be contacted or withhheld consent. Nine of these 13 patients were amongst those who had been tested at 1 and 4 weeks after treatment. At long-term follow-up, the group were receiving medication as follows: flupenthixol (9), chlorpromazine (2), pimozide (1), no medication (1). Two had never left hospital, two were re-admitted with an exacerbation of symptoms, five were living at home but unemployed and four were in employment.

In 13 depressed patients, recordings were obtained before treatment and 1 month after the start of treatment which was as follows: amitriptyline (7), cognitive therapy without drugs (2), monoamine oxidase inhibitor and lithium (2), ECT and amitriptyline (1), ECT alone (1). There were 59 control subjects, who included hospital staff, students and volunteers recruited through a local general practice. The control subjects had no history of physical or psychiatric illness and had been free of all medication for at least 12 months before testing.

Event-related potential recording

Event-related potentials were recorded soon after admission and repeated at 7–10 days and at 4 weeks after the start of treatment. A Nicolet CA1000 clinical signal averaging computer and NIC1009 P-300 stimulator were used (Nicolet Biomedical Instruments, Madison, Wisconsin). Subjects performed a two-tone auditory discrimination task while reclining in a chair in a sound-attenuated room. Bipolar recordings were made by way of a silver/silver chloride disc electrode secured at the CZ position and an indifferent ear-clip electrode attached to the left ear. The earth electrode was attached to the right ear. The electrode impedence was less than 2 kΩ. Sounds were delivered binaurally through headphones and the entire testing procedure lasted about 30 min. Subjects were instructed to count silently infrequent high-pitch tones of 1500 Hz randomly presented in a series of low-pitch tones of 1000 Hz. The ratio of high- to low-pitch tones was 1:9. The stimulus rate was 1.1/s, intensity was 65 db binaurally, and tone duration was 20 ms with a rise/fall time of 9.9 ms. The EEG was amplified 10 000 times with a bandpass of 1–100 Hz (−3 dB attenuation points of 12 dB/octave roll-off). The responses to frequent and rare tones were averaged separately. The digitizer sample rate was 100 kHz. The sensitivity was 50 μV. An artefact reject circuit excluded trials in which the voltage exceeded 45 μV. A total of 500 trials were averaged with a sweep time of 750 ms and a 75-ms pre-stimulus baseline. Two separate recordings were carried out at each testing. The baseline was estimated from the averaged response to frequent tones over the 75 ms before stimulus.

Individual peaks, designated N1, P2, N2, P3 (Fig. 1), were identified by visual inspection of the pen-recorded trace by a consultant neurophysiologist (D.M.McI.) who was not informed of the subject's diagnosis. N1 was the maximum negativity in the region of 70–120 ms and P2 the maximum positive deflection between 140 and 230 ms in the average response to frequent stimuli. P3 was the positive wave between 265 and 500 ms in the averaged response to rare stimuli and N2 was the negative deflection immediately preceeding P3. Latencies were measured at the maximum of amplitude using a cursor on the Nicolet CA1000 visual display. In those cases where the P3 deflection did not form a single sharp peak, the latency was measured as the point

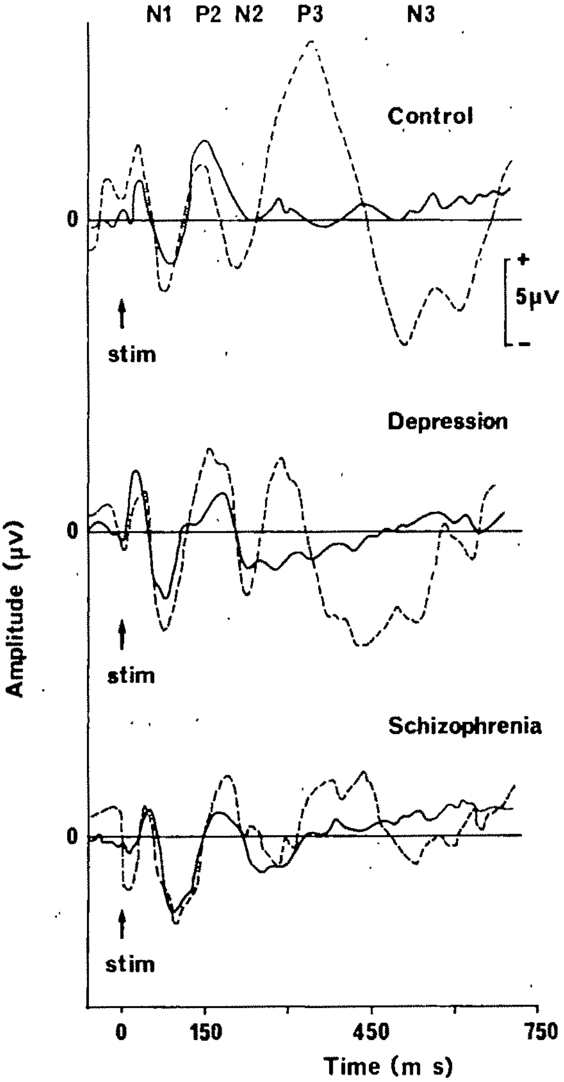

FIG. 1 Representative recordings of auditory event-related potentials obtained during a two-tone discrimination task from a control subject, a patient with major depressive disorder and a patient with schizophrenia. The continuous line is the response to frequent (1000 Hz) tones and the dotted line is the response to rare (1500 Hz) tones. In depression, P3 amplitude is reduced. In schizophrenia, P3 shows both a reduction in amplitude and an increase in latency.

of intersection of the tangents to the upgoing and downgoing slopes, measured on the pen-recorded trace. Amplitudes were measured from baseline to peak from the pen-recorded trace.

Results

Table I shows the age and sex distributions of all subjects and the clinical ratings of the patient groups. In each group, ages were normally distributed. In the control group, the latency and amplitude of the evoked potentials did not correlate significantly with age. Total BPRS scores were similar in both patient groups before treatment was started.

TABLE I
Age and sex distribution and clinical ratings of patients

	Male:female	*Mean age (range) (years)*	*BPRS mean ± s.e. (range)*	*Hamilton score mean ± s.e. (range)*
Control (59)	27:32	38 (19–59)		
Schizophrenic (24)	14:10	34 (19–57)	20.3 ± 1.5 (4–33)	11 ± 1.5 (1–30)
Depressed (16)	5:11	41 (19–60)	19.9 ± 2.2 (4–41)	24.3 ± 1.5 (17–37)

The latencies and amplitudes of the components of the evoked potentials were tabulated separately for the three subject groups. The results were then transposed on to the Edinburgh University mainframe computer and analysed using the *Statistical Package for the Social Sciences* (Nie *et al*, 1970). The data conformed to normal distribution and were analysed by one-way analysis of variance. The significance of differences between means was tested using the Scheffe procedure. However, in the analysis of P3 latency, the variances of the three groups were not homogeneous even after log transformation and differences between groups were tested separately using the Kruskall–Wallis test. Both the parametric and non-parametric analyses gave similar results.

Tables II and III show the mean latencies and amplitudes of N1, P2, N2 and P3 before treatment. The latencies of N2 and P3 were prolonged in the schizophrenic group and not in the depressed group compared with in control subjects. In 12 of the schizophrenic patients, P3 latency was greater than 2 s.d. from the mean of the controls. None of the depressed group came outside that range. The amplitudes of N1, P2, N2 and P3 were reduced in both depression and schizophrenia, but this reached significance only for P3 (ANOVA: $F = 11.95$, $P < 0.001$). Table IV shows the mean values for latency and amplitude of N1, P2, N2 and P3 in 14 patients with schizophrenia, in whom recordings were obtained before treatment and at 1 and 4 weeks after treatment began. The mean BPRS score was 20.9 ± 1.8 (range 16–33) before treatment, 21.0 ± 1.1 (range 16–27) at 1 week and 8.6 ± 1.7 (range 0–23) at 4 weeks. The change in BPRS over 4 weeks was significant ($P < 0.005$; paired t-test). One week after treatment, the latencies and amplitudes of the auditory responses were not altered significantly, but after 4 weeks, N1 amplitude was reduced and P2 amplitude was increased ($P < 0.01$; paired t-test). The latency and amplitude of N2 and P3 in schizophrenic patients did not change with treatment.

Table V shows the mean latencies and amplitudes of evoked responses before and during treatment in 13 depressed patients. The mean Hamilton Score was 24.7 (range 17–37) before treatment, and 6.0 (range 0–15) after

TABLE II

4 weeks after treatment started	97.4 ± 3.5	162 ± 4.4	223 ± 7.1	301 ± 8.4	2.8 ± 0.44**	4.6 ± 0.41	4.1 ± 0.91	8.3 ± 0.72*

*P3 amplitude increased, $P<0.05$ (paired Student t-test).
**N1 amplitude reduced, $P<0.005$ (paired Student t-test).

4 weeks of treatment. After 4 weeks of treatment, there was reduction in N1 amplitude ($P<0.005$; paired t-test). P3 amplitude was also increased to 8.3 ± 0.72 μV ($P<0.05$; paired t-test) at which value it did not differ significantly from that in the control group (8.9 ± 0.37 μV).

Long-term follow-up of patients with schizophrenia

The mean P3 latency of this group of 13 patients at initial assessment, when medication-free and acutely ill, was 341 ± 36 ms and the mean P3 amplitude was 6.6 ± 3.7 μV. When retested an average of 13 months later (range 6–24 months), the P3 latency was 342 ± 32 ms and the amplitude was 7.8 ± 4.3 μV. The mean BPRS score was 19.5 (range 4–33) before treatment and 5.9 (range 0–14) at follow-up. Long-term neuroleptic treatment was thus not accompanied by significant changes in the P3 of patients with schizophrenia.

P3 wave form

In the schizophrenic group, the P3 waveform tended not only to be of lower amplitude but was broadened with a less clearly identifiable peak. The flattened waveform persisted following clinical recovery.

The effect of amylobarbitone sodium sedation

Five patients with schizophrenia and four patients with depression had received treatment with amylobarbitone sodium within 3 days but not less than 10 h before testing. The total dosage ranged from 60 to 600 mg. There was no significant difference in latency or amplitude of evoked response between the amylobarbitone-treated group and the completely drug-free patients.

Illness duration and P3 latency

The average number of years from onset of first psychotic illness in the schizophrenic group was 6.6 (range 3 months to ~~20 years~~). The correlation between P3 latency and illness duration was not significant ($r=0.32$; Spearman's Rank Correlation).

Clinical ratings and evoked potentials

For the 24 schizophrenic patients tested before treatment, the Pearson's product moment correlations were calculated for P3 latency and amplitude with the total score and individual items of the BPRS and the total Hamilton Score. P3 latency correlated positively with the total BPRS score ($r=0.5$, $P<0.02$) and, of the 19 individual items which constitute the BPRS, only one (the symptom 'emotional withdrawal and deficiency in relating to others') had a significant positive correlation with P3 latency ($r=0.48$, $P<0.03$). In contrast, P3 amplitude was found to be related to mood disturbance. In patients with schizophrenia, there was a significant negative correlation between P3 amplitude and total Hamilton Score ($r=-0.5$, $P<0.01$) and, of the 19 individual items of the BPRS, P3 amplitude correlated negatively with 'depressive mood' ($r=-0.47$, $P<0.03$) and motor retardation ($r=-0.44$, $P<0.05$). In contrast, in the group of 16 depressed patients, P3 latency and amplitude did not correlate significantly with the total Hamilton Score, total BPRS score or any of the individual items in the BPRS schedule.

Discussion

The main finding in this study is that, in a group of patients with schizophrenia, the latency of P3 was longer than that in either depressed patients or controls and is in keeping with the report of Pfefferbaum *et al* (1984). In 12 out of the 24 schizophrenic subjects tested, the latency of P3 was in excess of 2 s.d. from the mean for the control group. These latency differences remained unchanged after 4 weeks of treatment with neuroleptics and at long-term follow-up, at which times there was marked improvement in clinical symptoms. The significant positive correlation between P3 latency in schizophrenia not only with the total BPRS score but also on the individual rating of emotional withdrawal and deficiency in relating to others contrasted with the poor correlation between P3 latency and positive symptoms of acute psychoses, such as the presence of hallucinations, affective symptoms and paranoid ideation.

P3 latency in the schizophrenic group of patients was not related to age, the duration of illness nor the use of amylobarbitone sodium for initial sedation. The constancy of the P3 latency and amplitude changes following treatment and partial remission of psychiatric symptoms, suggests that these measures in schizophrenia reflect an underlying disorder of the processing of auditory information and are not merely the result of attentional deficits accompanying an acute psychiatric illness. As a group, the depressed patients had a mean BPRS score similar to the schizophrenic group, and in three of the depressed patients normal P3 latencies were recorded despite auditory hallucinations being reported during the period of testing.

In groups of schizophrenic patients, significant abnormalities have been detected in a variety of other psychophysiological measures, including skin conductance responsivity (Gruzelier & Venables, 1972), pursuit eye movements (Holzman *et al*, 1973) and the P50 wave of the auditory-evoked response using a conditioning-testing paradigm (Adler *et al*, 1982). A relative between abnormal eye-tracking movements and skin conductance habituation (Bartfai *et al*, 1983) and between eye-tracking dysfunction and P50 response (Siegel *et al*, 1984) has been reported in schizophrenic subjects. Furthermore, both the P50 response and eye-tracking movements are abnormal in a significant proportion of close relatives of schizophrenics. The P300 response shares several characteristics in common with the skin conductance response (Roth, 1983) and further systematic studies into the relationship between P3 and other psychophysiological abnormalities in patients and their relatives may clarify the role of physiological tests in the identification of a subgroup of schizophrenics, who appear to have, as a trait marker, a defect in the processing of and response to auditory and possibly other modes of input.

There was a tendency for the amplitudes of N1, P2, N2 and P3 to be reduced in both depressives and schizophrenics, although significance between group means was reached only for P3. When the effect of treatment in both groups was examined using paired samples, a significant reduction in the amplitude of N1 and an increase in P2 was measured. It is difficult to interpret changes in these wave forms, since the inter-stimulus interval is one of the major determinants of amplitude of N1 and P2, and the interval of 1.1 s used in this study is well below the optimum 8-s interval required for maximum evoked potential size, and under these conditions an amplitude change may be a reflection of an altered recovery curve rather than a true amplitude change (Lader, 1977). However, a possible explanation for the reciprocal changes in N1 and P2 is that treatment may be followed by an attentuation of the broad negative wave (Nd) which extends beyond N1 into the latency range of P2 and which Hillyard & Kutas (1983) have shown to be generated in selective attention tasks.

A reduction in P3 amplitude and an increase in P3 latency, although capable of distinguishing a group of patients with schizophrenia from patients with major depressive disorder and control volunteers, are changes which are not specific to schizophrenia. Similar alterations in P3 are found in Alzheimer's but not Korsakoff's dementia (Pfefferbaum *et al*, 1984; St Clair *et al* (1985) and in mental handicap of Down's syndrome and fragile X syndrome (Blackwood & St. Clair, in preparation). Although the sensitivity and specificity of auditory-evoked potential changes in schizophrenia await to be defined, these results suggest the presence of a stable abnormality in auditory information processing in a considerable proportion of patients with schizophrenia.

Nuclear Magnetic Resonance Brain Imaging in Chronic Schizophrenia

J. A. O. BESSON, F. M. CORRIGAN, G. R. CHERRYMAN and F. W. SMITH

Patients with chronic schizophrenia were examined by nuclear magnetic resonance imaging of the brain. Subgroups of the syndrome with high positive or high negative symptom scores and ventricular dilatation were compared with each other and with normal controls in respect of regional spin lattice relaxation time (T_1) changes. Significant differences were not observed between the schizophrenic subgroups and controls but there were significant differences between the subgroups themselves. The presence of tardive dyskinesia was associated with increased T_1 of the basal ganglia. The significance of these results is discussed in relation to findings using other techniques.

The development of newer imaging techniques has allowed the investigation of patients with schizophrenia in a manner hitherto difficult to achieve. Early reports by Johnstone *et al* (1976) demonstrated the presence of increased ventricular size and cognitive impairment in a group of chronic schizophrenics. Younger patients (Trimble & Kingsley, 1978; Benes *et al*, 1982) were shown to have normal ventricular dimensions. Weinberger *et al* (1979, 1980) did not find any correlation between ventricular size and length of illness, but found that those with atrophy had a poorer premorbid adjustment and a poorer response to neuroleptics.

In monozygotic twin studies, Reveley *et al* (1982) observed that the schizophrenic proband had enlarged ventricles compared with those in controls, suggesting that this is not a result of medication or chronicity and furthermore (Reveley *et al*, 1984) that it is a feature of those patients with a history of perinatal morbidity.

Golden *et al* (1980) showed a relationship between those with increased ventricular size, cognitive impairent and the presence of reduced X-ray density especially in the left anterior half of the brain.

Regional spin lattice relaxation time (T_1) changes obtained during nuclear magnetic resonance (NMR) imaging employing the spin-warp technique of Johnson *et al* (1981) have been demonstrated to alter in a number of pathological processes affecting the brain. These vary very widely and occur to a substantial degree in tumours, areas of demyelination and vascular lesions and, to a lesser degree, in Alzheimer's disease (Besson *et al*, 1985*a*) and idiopathic Parkinson's disease (Besson *et al*, 1985*b*). Thus, changes in T_1 may be used as an indicator of the site of pathological change. This study investigates patients with schizophrenic illness to determine:

(a) whether there are areas of the brains of schizophrenics which have altered T_1 compared with that of normals;
(b) whether there is a relationship between clinical profile, ventricular size and T_1 change;
(c) whether schizophrenic patients with tardive dyskinesia have changes in T_1 differing from those without.

Method

Twenty-three patients with a diagnosis of schizophrenia (DSM-III) were imaged. There were 20 males and three females, with a mean age of 36 years (Range 21–58 years) and a mean duration of illness of 12 years (range 1–36 years). All patients were receiving a dosage of neuroleptics considered optimal for their clinical state. The controls were 15 normal subjects, 12 males and three females, with a mean age of 36 years (range 21–54 years).

Imaging was carried out using the Aberdeen Mark II NMR imager (Hutchison *et al*, 1980), field strength 0.08 T, resonance frequency 3.4 MHz. Midline saggital and coronal sections were taken. From the sagittal section, regions of interest were mapped in the genu and splenium of the corpus callosum and in the thalamus; and from the coronal section, regions of central white matter of the temporal lobe and medial temporal structures corresponding to the inferior limb of the limbic system were mapped. Transverse sections commencing at the orbitomeatal level and moving cranially at 1-cm intervals were taken and regions of interest mapped in the basal ganglia, frontal and parietal white matter of both sides. The area, pixel count coordinates and mean ± s.d. T_1 values were obtained for each region of interest by computerised recall of the original acquired data.

Ventricular size was rated by visual examination of the images by an independent radiologist who was rating blind to the other aspects of the study. Ventricular size was rated on a four-point scale, with 0 indicating normal size and 3 the largest ventricles of the sample.

Subjects were rated for positive and negative symptoms by a semi-structured interview using a modified schedule of Krawiecka *et al* (1977). The presence of delusions, auditory hallucinations, incongruity of affect and altered mood were included in rating as positive symptoms, and blunted affect, psychomotor retardation, poverty of speech and incoherence or irrelevance of speech as negative. Each patient was examined for the presence of tardive dyskinesia using the items of the AIMS scale.

Results

Ventricular dilatation, clinical characteristics and regional T_1 values

Twelve patients had normal ventricular size and 11 had dilated ventricles. Of these 11, four were severe, one moderate and six were mild.

Comparing the normal and the dilated ventricular groups, there was no difference in the T_1 values in any of the regions of interest measured. With regard to the clinical features, there was no difference in the level of positive symptoms between the two groups, but the abnormal group had a slight increase in negative symptom score but this was not statistically significant. Those with dilated ventricles had a longer history of illness (mean 17 ± 4 years, compared with those with normal ventricles: 9 ± 2 years, NS) and were older (42 ± 4 years compared with 30 ± 3 years, $P = 0.02$). Those with dilated ventricules had slightly increased numbers with tardive dyskinesia, but this was not statistically significant.

Clinical subgroups based on cluster analysis of positive and negative symptom scores

Patients were rated on the basis of their positive and negative symptom scores on the Krawiecka scale and clustered into four groups on the basis of whether they scored high or low on the positive symptom and negative symptom dimensions. High positive patients had a mean score of 2.6 (range 0–4) and low positive patients had a mean score of 7.4 (range 5–10). Low negative patients had a mean score of 3.4 (range 2–4) and high negative patients had a score of 7.2 (range 5–10). Using this method four groups were obtained:

(1) low positive, high negative ($n = 6$);
(2) low positive, low negative ($n = 8$);
(3) high positive, low negative ($n = 4$);
(4) high positive, high negative ($n = 5$).

The T_1 characteristics of each region of interest measured were compared in each of the four groups. Group 1, characterised by a high negative score, had significantly increased T_1 (283 ± 5 ms) in the left frontal white matter compared with that in group 3 (265 ± 4 ms, $P < 0.05$) which is characterised by low negative scores. Significant differences were not found between the other groups, nor when each group was compared with controls (274 ± 4 ms).

Groups 3 and 4, characterised by high positive scores, had significantly increased T_1 in left medial temporal structures (368 ± 12 and 362 ± 11 ms respectively) compared with that in group 1 (348 ± 16 ms, $P < 0.05$) — characterised by low positive scores. Significant differences were not found between the other groups, nor when each group was compared with controls (360 ± 10 ms).

The ventricular sizes were examined in the four groups. In group 1 ($n = 6$), three patients had normal ventricles and three abnormal (one mildly dilated, one moderately dilated and one severely dilated). In groups 2 ($n = 8$), six were normal and two mildly abnormal. In group 3 ($n = 4$), three were normal and one mildly dilated, and in group 4 ($n = 5$), none were normal, two mildly dilated and three severely dilated. The most abnormal group (group 4) were characterised by high positive and high negative scores, and those with high negative scores alone (group 1), the next most abnormal, in terms of ventricular dilatation. Using the generalisation of Fisher's Exact Probability Test, the groups were different at the $P < 0.05$ level, the major contribution being from group 4.

Basal ganglia and tardive dyskinesia

Schizophrenics with tardive dyskinesia were compared with those without and with normal controls. The T_1 measures of all regions of interest, except for the basal ganglia, did not differ between these three groups. Differences were found in the putamen–globus pallidus of the basal ganglia (Fig. 1).

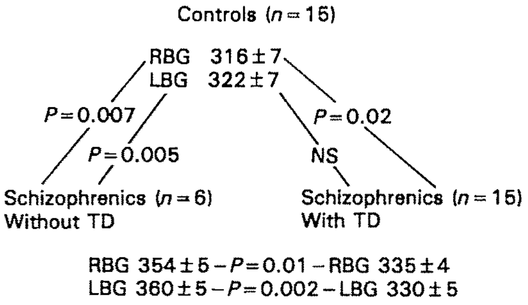

FIG. 1 Right and left basal ganglia T_1 (ms, mean ± s.e.).

Patients with tardive dyskinesia had significantly higher T_1 values than had normal controls. There were also significant differences between those with tardive dyskinesia and those without.

Tardive dyskinesia did not correlate with positive or negative symptom score, age or length of history. Three of the six patients with tardive dyskinesia had normal ventricles and three had mild or moderate ventricular dilatation. Patients with ventricular dilatation did not have statistically significantly higher tardive dyskinesia scores than those without ventricular dilatation.

Conclusion

The spin lattice relaxation time measured during NMR imaging is a sensitive indication of pathological processes. The precise nature of the pathological process is not disclosed accurately by these measures, but they are nevertheless useful in morphological siting of pathological lesions.

This study confirms previous reports that there is a subgroup of patients with schizophrenia who have enlarged ventricles, and these tend to have a high level of negative symptoms. Those with high negative and high positive scores tend to have the largest ventricles and are presumably the most severely ill.

High negative scorers have increased T_1 in the left frontal region in comparison with that of low scorers. This is of interest in view of the reputed reductions in cerebral blood flow and glucose utilisation in that region in positron emission tomographic (PET) studies (Buchsbaum *et al*, 1982) and the reduced X-ray density in computerised tomographic (CT) studies (Golden *et al*, 1980). However, these differences do not differ significantly from controls.

The negative symptoms in chronic schizophrenia bear a certain likeness to the frontal lobe syndrome seen in organic states. X-ray CT and NMR studies raise the possibility of morphological change in the frontal area. This is compatible with the reduced glucose utilisation and reduced cerebral blood flow in the frontal regions observed during PET studies by Buchsbaum *et al* (1982). Thus, the reduction in metabolic activity may be linked to structural change.

High positive symptom scorers have increased T_1 in the left medial temporal area relative to low positive scorers but not to controls. These schizophrenic subgroups do not differ from controls in respect to left medial temporal T_1 changes, but differ from each other.

All patients had received neuroleptic medication for prolonged periods of time and at varying dosage. Length of illness as a general rule relates to length of neuroleptic treatment. Tardive dyskinesia score does not correlate with length of illness. T_1 changes are found both in patients with and without tardive dyskinesia, although they were greater in the former. Therefore these changes may relate either to the presence of neuroleptic *per se* or to some change occurring as a result of the neuroleptic which may present to a lesser degree in patients without tardive dyskinesia and more pronounced in those with tardive dyskinesia and suggest an underlying pathological process associated with this disorder.

It is of interest that the neuroleptic-free patients of Buchsbaum *et al* (1982) showed reduced glucose metabolism in the central grey matter areas (mainly caudate) mainly on the left. There were no drug-free patients in this study, but any change in T_1 of the schizophrenic group without tardive dyskinesia only reached significance on the right. The striking differences occur in patients with tardive dyskinesia and suggest a location of pathology of this disorder in the basal ganglia. Such changes are also present in patients without tardive dyskinesia who are on medication. As yet, we do not know whether these changes are present in untreated schizophrenics, and whether therefore they are a feature of the disease which is present in greater magnitude in those with tardive dyskinesia from onset, or acquired later.

Tiapride in the Long-term Management of Alcoholics of Anxious or Depressive Temperament

G. K. SHAW, S. K. MAJUMDAR, S. WALLER, J. MACGARVIE and G. DUNN

Thirty-two chemically dependent alcoholics with significant levels of anxiety or depression were admitted to a double-blind randomised study in which the effect of the substituted benzamide tiapride was compared with that of placebo over a 6-month period. Twenty patients completed the study. Assessments included relevant biochemical and haematological tests, drinking levels and associated behaviour, expressed satisfaction with various areas of life, the Crown–Crisp Experiential Index of neurotic symptoms and questionnaires on self-esteem and alcohol dependence. The results indicated that in comparison with the placebo group, patients treated with tiapride drank less and had longer periods of abstinence. This was associated with improvements in laboratory tests, reduction in neurotic symptoms, gains in self-esteem and increased levels of expressed satisfaction with life situation. The drug was well tolerated and no deleterious effects were noted, suggesting its potential usefulness for this patient group.

This paper reports a study assessing the efficacy of tiapride as a treatment agent in chemically dependent alcoholics with significant symptoms of anxiety or depression.

Treatment of chemically dependent alcoholics is not universally successful and depressed or anxious alcoholics present special problems. The use of antidepressants carries the risk of facilitating suicide in a high-risk group, and the long-term use of minor tranquillisers not only increases the risk of suicide but also enhances dependency, both to alcohol and to the minor tranquilliser. Thus, those patients are frequently denied the benefit of drugs which might alleviate some of the symptoms likely to encourage further drinking on their part.

Tiapride (N-diethylaminoethyl 2-methoxy-5-methylsulphonyl benzamide) is a member of the substituted benzamide group of drugs which include metoclopramide (an antiemetic) and sulpiride (an antipsychotic). It is a selective dopaminergic receptor blocking agent (Costall & Naylor, 1977), but differs from typical neuroleptics in that it is not sedative (Jenner & Marsden, 1979) and does not cause Parkinsonism (Jenner *et al*, 1978). In common with typical neuroleptics, no anticonvulsant effect has been reported (Parent *et al*, 1978). It is not a drug of addiction (La Barre, 1978).

The drug has attracted favourable attention in the literature on the management of alcoholism. It has been found to have beneficial effects on tremor, agitation, gastrointestinal disturbance, appetite and craving for alcohol. Favourable results have been reported on the symptoms of anxiety (Marx, 1981; Bonnaffoux *et al*, 1982; Peyramond, 1982) and on symptoms of depression (Bonnaffoux *et al*, 1982; Stecchini & Corrias, 1982). In an earlier study from our own unit (Murphy *et al*, 1983), tiapride was found to have beneficial effects on symptoms of anxiety and depression. It was observed that the drug did not affect vigilance and there was a suggestion that it alleviated craving for alcohol. Freour (1979) reported facilitation of abstinence with the drug and Bonnaffoux *et al* (1982) reported an improvement in relationships within the work and family setting.

The non-addictive nature of the drug, its beneficial effects on symptoms of anxiety and depression and the possibility that it might lessen craving for alcohol suggested its usefulness in the long-term management of alcoholics of anxious or depressive temperament.

Treatment of alcoholism aims not only to promote abstinence but also to improve the alcoholic's ability to function in a social setting and to increase satisfaction, both with regard to relationships with significant others and with general life-style. Therefore, the study was designed to take account of those factors.

Method

The study was double-blind and placebo-controlled with random allocation to groups. Consecutive male admissions to the detoxification section of an alcohol treatment unit in 1983 and 1984 were admitted to the study, after routine detoxification procedures had been completed, if they fell in the age range 25–65 years, were assessed clinically chemically dependent on alcohol, gave current evidence of high levels of anxiety or depression, scored more than 30 on the Crown–Crisp Experiential Index (Crown & Crisp, 1979) towards the end of their period of detoxification and whose life history gave evidence of a tendency to react to adverse life situations with manifestations of anxiety or depression. Informed consent was obtained from all patients, who were then allocated randomly to an active group who received tiapride 100 mg *t.i.d.* for a period of 6 months or to a placebo group who received one identical dummy tablet *t.i.d.* for the same period.

At the time of admission to the study and at closure, a battery of laboratory investigations were carried out (haemoglobin, mean corpuscular volume, platelet count, total bilirubin, alkaline phosphatase, aspartate transaminase, γ-glutamyl transpeptidase and albumin).

At intake, each patient was interviewed by a sociologist and two schedules were completed. The first schedule collated demographic information about the patient and, taking as point of reference the six months prior to admission, data relating to employment, the use of medical, psychiatric or alcohol facilities, the use of social agencies and criminal involvement. The drinking history over the previous 6 months was examined in detail and data recorded in relation to the number of days drinking in the previous 6 months, the quantity drunk on drinking days, the complications and consequences of drinking and the social complications of drinking. The total years of heavy drinking and the number of years since excessive drinking had been regarded as a problem were also recorded.

The second schedule was completed by both the patient and the sociologist. Assessments were made of the quality of the relationships with spouses, relatives and friends, and of the degree of satisfaction with employment status, accommodation, use of leisure time and physical and mental health. At this time, the patient completed a questionnaire assessing self-esteem (Litman *et al*, 1983), a questionnaire assessing dependence on alcohol, the Severity of Alcohol Dependence Questionnaire (SADQ) (Stockwell *et al*, 1979) and the Crown–Crisp Experiental Index. Each patient was re-interviewed at monthly intervals throughout the trial, when compliance with treatment was assessed by estimating the number of tablets left and a further 1-month's supply of tablets was issued. Significant changes in social functioning were noted and details of drinking behaviour over the previous month were recorded.

At completion of the study, the schedules were completed — on this occasion with reference to the 6-month study period. The self-esteem index and the Crown–Crisp Experiential Index were also repeated.

Data collected at monthly follow-up interviews were not analysed separately but were used to improve the accuracy of the final rating schedules. The pre- and post-treatment scores of pathological investigations were analysed statistically using the Statistical Analysis System (SAS) and the data from the schedules using the SAS system backed up where appropriate by non-parametric Willcoxon tests.

Results

A total of 32 patients entered the study, of whom 13 received tiapride and 19 placebo. Seven of the latter failed to comply with follow-up; they were all of no fixed abode. Of the active group, two patients were lost as they removed from the area, 2 patients of no fixed abode did not comply with the protocol and one was withdrawn because of intercurrent physical illness (congestive cardiac failure) unrelated to trial treatment. Those who dropped out were similar to the others in age and in length of drinking history but appeared to be more disturbed. For instance, they were more neurotic, more dependent on alcohol and over the preceding 6 months had longer periods of unemployment, spent more time in hospital and had suffered more arrests. However, the main difference was that 75% of them were homeless, as opposed to 15% of those who completed.

A comparison of the active group (8 patients) with the placebo group (12 patients) found them to be well matched in respect of demographic data, drinking history, severity of dependence and on various biochemical parameters. None of the differences between the groups was statistically significant.

Conventional liver function tests and routine haematology were carried out before and after treatment in both the tiapride and placebo groups. Those patients treated with tiapride showed beneficial changes on all tests performed and in the case of mean corpuscular volume the change achieved statistical significance (94.75 ± 7.76 *vs* 87.50 ± 6.55 fl). In contrast, the patients treated with placebo showed no change in mean corpuscular volume (96.75 ± 6.63 *vs* 96.27 ± 6.32 fl), an increase in alkaline phosphatase (85.75 ± 28.56 *vs* 101.30 ± 102.62 IU/litre), and a fall in albumin levels (42.42 ± 7.22 *vs* 36.10 ± 3.21 g/litre), these adverse changes no doubt reflecting continued drinking.

Changes in various drinking parameters before and after treatment in the tiapride and placebo groups are listed in Table I. In the tiapride group there were significant improvements in the number of days abstinent, physical complications of drinking and average daily intake on a heavy drinking day. All other changes were in a beneficial direction. These improvements were not mirrored in the placebo group and in some instances changes have been adverse. It will be seen from a comparison of columns 1 and 3 that the groups were well matched prior to treatment and there was no significant difference between the groups on any variable.

Pre- and post-treatment scores obtained on the Crown–Crisp Experiential Index and Self-esteem Scale in the tiapride and placebo groups are listed in Table II. A comparison of pre-treatment scores in the tiapride and placebo group shows no significant differences between the groups. In the case of the tiapride group, there were significant beneficial changes in all measures, whilst no change was observed in the case of the placebo group.

Table III lists the percentage of patients expressing improvement in level of satisfaction with various social and health functions in both tiapride and placebo groups. It is clear that the patients in the active treatment group were markedly more satisfied with their level of functioning after

TABLE I

Indices of drinking before and after treatment in the tiapride and placebo groups

Items (mean ± s.d.: range)	Tiapride Pre-treatment (n = 8)	Tiapride Post-treatment (n = 8)	Placebo Pre-treatment (n = 12)	Placebo Post-treatment (n = 12)
Average daily intake of ethanol (units) on a heavy drinking day	44.38 ± 23.25 (16–86)	22.5 ± 16.69** (0–48)	41.92 ± 22.18 (14–92)	39.67 ± 29.27 (0–92)
Total days abstinent in preceding 6 months	36.13 ± 48.48 (0–126)	102.88 ± 70.34* (28–182)	40.33 ± 41.34 (0–133)	57.42 ± 66.99 (0–182)
Physical complications	3.38 ± 1.41 (1–5)	1.88 ± 1.64* (0–4)	4 ± 0.95 (3–6)	3.83 ± 1.99 (0–6)
Social complications	2.88 ± 5.06 (0–15)	1.25 ± 2.19 (0–6)	4.5 ± 7.05 (0–26)	8.08 ± 11.08 (0–32)
Use of medical and social facilities	28.13 ± 14.09 (1–46)	20.5 ± 14.83 (3–46)	18.5 ± 17.38 (3–66)	23.17 ± 17.34 (7–57)

*$P<0.02$; **$P<0.01$.

treatment as compared to the situation prior to treatment. In the case of the placebo group, improvement in satisfaction was, at best, modest. In a number of instances, the differences in improved satisfaction between groups achieved statistical significance.

Additional statistical comparisons were made of score changes before and after treatment across the tiapride and placebo groups on all variables, with the following results. In the case of pathological parameters, the fall in mean corpuscular volume was significantly greater in the tiapride group. In the case of drinking variables, the tiapride group fared better at a statistically significant level than the placebo group in respect of the average amount of alcohol consumed on a heavy drinking day, in respect of physical complications experienced and in the use made of medical and social facilities. In respect of the Crown–Crisp Experiential Index, the tiapride group fared better than the placebo group on all indices at highly statistically significant levels.

Discussion

This study was designed to assess the efficacy of tiapride as an aid in the longer-term management of chemically dependent alcoholics of anxious or depressive temperament. The severity of their symptoms of anxiety and/or depression is made evident from their pre-treatment scores on the Crown–Crisp Experiential Index (Table II), which all fall in the range of high pathology. Subjects scoring in this range would normally be treated either with conventional antidepressants or with minor tranquillisers. However, there is a reluctance on the part of clinicians to use these drugs in the alcoholic population, particularly since alcoholics are known to be a high-risk group in respect of suicide. Antidepressants are commonly used as suicidal agents and have peculiar dangers in that respect. The use of minor tranquillisers also increases the risk of suicide and carries the risk of substituting dependence on drugs for dependence on alcohol. There is also evidence (Smith & Wesson, 1983) that the use of alcohol increases the likelihood of developing dependency to benzodiazepines and it is probable that the use of benzodiazepines increases the ease with which dependence on alcohol may develop. Thus, these patients are usually deprived of the benefit of drugs which might alleviate some of the symptoms likely to encourage further drinking on their part.

Tiapride is not a drug of addiction and is therefore unlikely to enhance the development of chemical dependence on alcohol. It is relatively safe even if taken in high dosage and there is no evidence of synergistic reactions if combined with alcohol. Thus, the danger of successful suicide with the drug is less pressing. Its known antianxiety and antidepressant effects, coupled with the facts that it does not affect vigilance and may alleviate craving for alcohol, suggest its usefulness in the management of this patient group.

That subjects in this group are difficult to treat is confirmed from a consideration of our placebo group. Both tiapride and placebo groups, in addition to medication, had the benefit of regular supportive follow-up interviews conducted by therapists specialising in the treatment of alcoholism. Despite this, the placebo group showed no significant improvement over a 6-month period in a battery of pathological tests, in ratings of neuroticism, depression and self-esteem or in various measures of drinking status. Furthermore, improvement in their level of satisfaction with various measures of social functioning was, at best, modest.

The results of this study indicate that the tiapride group fared considerably better than did the placebo group. A consideration of changes in a battery of pathological tests before and after treatment offered no evidence of any deleterious effect of the drug on any of the parameters measured. In the case of the mean corpuscular volume, there was indeed a significant post-treatment shift in a beneficial direction.

The tiapride-treated group showed highly significant improvements in ratings of neuroticism, anxiety and depression as assessed by the Crown–Crisp Experiential Index, improvements which were not seen in the placebo group. In both groups, there was an improvement in self-esteem over the trial period, but only in the case of the tiapride group was the change of statistical significance.

With regard to various measures of drinking status over the treatment period, the tiapride group showed a significant increase in total days abstinent over a 6-month period and showed significantly less in the way of physical complications over that period. Their use of medical and social facilities and the number of social complications which they suffered were also reduced, although these did not achieve statistical significance. There was a highly statistically significant reduction in the amount of ethanol taken on a heavy drinking day. In contrast, the placebo group showed only modest improvement in respect of total days abstinent over the trial period, and their use of medical and social facilities increased, as did the number of social complications which they suffered.

Some indication that these improvements in drinking levels and in neurotic symptoms were accompanied by improved satisfaction with their life situation emerges from a consideration of Table III. In all instances, the tiapride group expressed much improved satisfaction in these areas whilst, at best, the placebo group made only modest gains.

This study is open to the criticism that the numbers are small, that the research questionnaires used by the sociologist have not been validated but rely on rather obvious face validity and that the research design did not allow complete confidence that patients were fully compliant with medication. Nonetheless, the results seem clear-cut. The tiapride group drank less, had longer spells of abstinence, improved significantly on measures of neuroticism and expressed greater satisfaction with their social situation and with their physical and mental health.

Acknowledgements

We would like to express our thanks to Delagrange International, who financially supported this study, to the Nursing Staff of Elmdene Ward, Bexley Hospital, and to Mrs Jean Johns for secretarial and administrative assistance.

Depression in the Elderly Living in the Community

Its Presentation and Features

O. BEN-ARIE, L. SWARTZ and B. J. DICKMAN

A prevalence of depression of 13% was found among 139 coloured persons aged 65 years and over, living in the community in Cape Town, which accords with figures elsewhere. A high rate of hypochondriasis was found, but there was a low rate of suicidal intent, which could be explained by good social support. Observed depression and a depressed mood occurred in almost all depressed patients; as defined in the Present State Examination, these items appear to be an excellent screen for depression.

A comprehensive survey of the psychiatric, physical and psychosocial status of non-institutionalised, coloured residents of Cape Town, aged 65 and over, was undertaken in 1982 (Ben-Arie *et al*, 1983; Elk *et al*, 1983; Nash & Meiring, 1983; Jacobs *et al*, 1984). They comprise a population group, living mainly in the Cape, who developed from the intermarriages of indigenous people and settlers (Gillis *et al*, 1968). This article examines the clinical features of depression in this group of elderly residents, and explores associated factors.

The clinical features of depression in the elderly have been summarised by Stenback (1980): depressed mood, somatic complaints and hypochondriasis are common, as are anxiety, irritability and loss of interest, but there is uncertainty about the prevalence of guilt and self-reproach. It has been argued that depression in old age is typified less by guilt than by somatic complaints, but Post is reported (Stenback, 1980) as having found symptoms of guilt and self-reproach in almost half his patients.

Epidemiological psychiatry has focused on the reliability and validity of psychiatric 'case' identification (Wing *et al*, 1981), and there is a particular problem in recognising depression in the elderly because it may present with features similar to dementia. To overcome such difficulties, research workers have turned to the use of instruments with proven validity and reliability for use in the elderly, such as the Comprehensive Assessment and Referral Evaluation Interview Schedule (CARE) (Gurland, 1980) and the Geriatric Mental State Examination (Henderson *et al*, 1983). The Present State Examination (PSE) (Wing *et al*, 1974; Wing & Sturt, 1978) is particularly useful because it is not age-specific and enables easier comparison with other age groups (Murphy, 1982, 1983).

Regardless of the instruments chosen, it is necessary to present data in a standard manner (Gurland *et al*, 1983; Henderson *et al*, 1983), while simultaneously respecting the uniqueness of the population under observation (Gutman, 1980).

Method

The survey as a whole

Selection of subjects

Names were obtained from geriatric registers kept by the City Health Department for the Eastern Zone of Cape Town. These are comprehensive registers of all persons of pensionable age (over 60 for females and 65 for males) compiled by community health nurses employed by the Department; they are continually updated by house-to-house visits. The Eastern Zone was chosen for sampling as it covers a representative range of income and social groups, as well as being the largest municipal zone.

A subsample selected at random was checked for representativeness by door-to-door enquiries, and consisted of evaluation of one street in each of ten areas chosen at random. A total of 20 consecutive houses per selected street were visited, and a list was drawn up of all people aged 65 and over. This was then compared with the relevant street registers, and there was a 75% agreement, without a particular pattern of non-correspondence in terms of age, sex, area and income variables. Using a table of random numbers, 150 respondents of 65 years and over were selected from the same subsample (Elk *et al*, 1983). The total number of elderly people on the Eastern Zone register was 9617, and the sampling rate was therefore greater than one in 64.

Procedure

Psychosocial data and subjective assessments of physical health were obtained through home visits by a team of six research workers (clinical psychologists and social workers) specially trained in the use of the instruments chosen for collection of the data. Within 2 weeks, respondents were examined physically by a team of doctors and assessed psychiatrically at community health centres by ten psychiatrists and clinical psychologists, specially trained for this purpose. There was one refusal for the study as a whole, and ten subjects did not have the psychiatric examination, one having died shortly after initial assessment and another, being deaf and blind, could not be assessed by the instruments used. The remainder refused to attend clinics or to allow domiciliary follow-up for a variety of personal reasons.

Assessment methods

The Present State Examination (PSE) (Wing *et al*, 1974) has been found to be reliable in many in-patient and population studies (Wing *et al*, 1977, 1978). It consists of 140 ratable items, from which syndromes can be generated by the CATEGO computer program. When the number, type and severity of symptoms cross the threshold of an index of definition (ID) (Wing & Sturt, 1978), a tentative diagnosis according to the eighth revision of the *International Classification of Diseases* is generated.

The Social Performance Index (Hurry & Sturt, 1980) is a measure of coping, and examines performance in seven well-defined areas (household, employment, money management, child care, intimate and non-intimate relationships, and social presentation). Respondents are rated only on items which apply to them, and ratings based on the person's report of the family's expectations, which has the disadvantage of losing direct comparability of scoring. A total impairment score is calculated for each respondent.

The Mini-Mental State Examination (MMSE) (Folstein *et al*, 1975) was developed for the assessment of intellectual impairment by a standard short rating scale and was mainly intended for use in elderly patients. However, in this investigation, it was adapted for use in a community survey. In view of the high illiteracy rate in the population studied, which is known to bias results (Anthony *et al*, 1982), these were interpreted conservatively, and an additional criterion of impaired social performance was required before a person could be rated as demented (Ben-Arie *et al*, 1983).

Selection of subjects for the current study

The current study examined differences in symptoms between depressed and 'well' respondents, i.e. those not given a diagnosis by the psychiatric ratings used. Respondents with a level of cognitive impairment likely to affect assessment ($n = 18$) were excluded using the MMSE and Social Performance Scale, as were those with diagnoses other than depression ($n = 10$). Diagnostic decisions were based on a combination of PSE findings and independent clinical assessment (Ben-Arie *et al*, 1983). Diagnoses other than depression or dementia included paranoid states ($n = 3$), schizophrenia ($n = 2$), mania ($n = 1$), and personality disorders ($n = 4$). No neurotic conditions (other than neurotic depression) were diagnosed, but 5% of the respondents (15% of males and 0.9% of females) were rated as being dependent on alcohol which, however, was not used as a criterion for exclusion. The depressed group, as based on the PSE/CATEGO tentative diagnosis, consisted of 23 respondents (16.5% of the respondents who were assessed psychiatrically). This group was re-analysed because it is possible to generate a tentative CATEGO diagnosis of depression on the basis of a single anxiety symptom (anxiety, panic attacks or anxiety on examination). Furthermore, the threshold ID of 5, which is sufficient for a tentative CATEGO diagnosis to be made, may tend to over-diagnose in population studies (Wing *et al*, 1981).

Therefore, the PSE protocols of the 23 respondents with a CATEGO tentative diagnosis of depression were examined further by two independent psychiatrists, experienced in the PSE but blind to the ID level. The raters agreed independently that the same four respondents were not clinically depressed; all had an ID of 5 (three scored on anxiety symptoms alone, and one had anxiety symptoms plus mild slowness of speech and observed depression). Therefore, these cases were excluded from further analysis, and their symptom profiles are shown in the Appendix.

The final samples for comparison thus consisted of 19 clinically depressed respondents (13.7%) and 88 with no psychiatric diagnosis (63.3%).

Results

Description of the group as a whole

The respondents were in general a 'young old' group (modal age category: 65–69 years) and mainly female (73%). Approximately one-third were married, half widowed and the remainder single or divorced. Over 70% had had less than 7 years of schooling, 21% never having been to school. Personal income was generally equal to the government old-age pension, and 79% came from families where the breadwinner(s) had been unskilled labourers. The vast majority of respondents were either retired (66%) or housewives (26%), with only 1% in full-time and 6% in part-time employment. A total of 96% were living with family and the remainder with friends—none were living alone. Nutrition was considered to be generally satisfactory, as judged from a haematological analysis and dietary history, and in the few cases where malnutrition was found, this was associated with alcoholism or major physical illness (Jacobs *et al*, 1984).

Findings with regard to depression

All statistical analyses of the data were done by the likelihood ratio chi-square, unless otherwise stated.

Demographic features

There were no significant associations between depression and demographic features such as age, sex, marital status, previous occupation and personal and pooled family income.

Psychiatric symptoms

Of the 19 depressed respondents, six had a 'threshold' ID of 5, the remainder scoring 6 or more.

For the purpose of comparison between the depressed and non-depressed groups, psychiatric symptoms were dichotomised on a present/absent basis. Table I shows a comparison in frequency of symptoms making up the syndromes leading to the CATEGO tentative diagnosis of depression.

Table II shows that PSE symptoms not leading to a tentative diagnosis of depression which significantly differentiated the two groups. Where there were differences in the frequency of symptoms, these were always more common in the depressed group.

TABLE I

Previous psychiatric treatment

There were no differences between the two groups on reports of previous psychiatric treatment.

Use of medication and physical complaints

A significantly greater percentage of depressed respondents were on 'minor tranquillisers' (15.8% as opposed to 1.1% $P<0.01$) and on vitamins (26.3% as opposed to 8%, $P<0.05$). No respondent in either group was on antidepressants, nor were there other differences in the use of medication. Significant differences were found in the area of subjective physical complaints; of the depressed group, 31% reported stiffness in the joints to the extent that it affected their daily activities as opposed to 7% in the psychologically well group ($P<0.01$). This finding was not significantly related to osteoarthritis on physical examination or to antirheumatic drug use. Of the depressed respondents, 58% ($n=11$) as opposed to 8% of the well respondents ($n=7$) felt at least moderately incapacitated by a variety of other physical complaints such as chronic cough, varicose veins, dizziness and hypertension ($P<0.001$). Visual difficulties of at least a moderately incapacitating nature were reported by 53% of the depressed, as against 27% of the non-diagnosed respondents ($P<0.05$). This finding was supported by the fact that the significantly more depressed had problems with visual acuity on examination (90 *vs* 65%, $P<0.05$).

No significant differences between the groups were found in reports of pain, dyspnoea, urinary and faecal incontinence, hearing difficulties, or other pathology detected on physical examination. Six respondents were found to have carcinomas; one of these fell into the depressed group.

Associated psychosocial features

Social performance. The depressed group was significantly more impaired in overall social performance than was the well group (22% mean disability rating *vs* 11%; Mann-Whitney $U=598.5$, $P<0.05$), experiencing difficulty of at least moderate intensity in the areas of household management (HM), child management (CM) and non-intimate relationships (NIR) (HM: 67 *vs* 27%, $P<0.01$, $n=103$; CM: 62 *vs* 10%, $P<0.001$, $n=54$; NIR: 42 *vs* 16%, $P<0.05$, $n=104$). Different totals for items arise because not all sections of the Social Performance Index were applicable to all respondents.

On multi-dimensional analysis, it emerged that over half of the depressed respondents (56%) had difficulty with household management, together with reported stiffness and other physical complaints. Only 7% of the control group reported difficulties in these areas. Assessments of household management performance took physical problems into account, since this is assessed by using the person's expected level of physical ability as a baseline.

Discussion

The prevalence of depression in elderly persons living in the community as shown in this study (13.7%) is similar to that of other investigations (Kay & Bergmann, 1980; Stenback, 1980). The putative protective effect of stable and supportive social groups in preventing depression does not seem to have lowered its rate in this population (World Health Organisation, 1983). The combined use of the PSE and independent clinical judgment probably makes the identification of depression as accurate as is possible for a community survey. In this study, the random sample revealed a higher proportion of females (73%) than of males. This is in keeping with, but higher than the proportion of females in this population in the Greater Cape Town area—61% in the 1980 census. Our sampling procedure was extremely rigorous and all possible precautions were taken to eliminate sampling errors. The difference may be due to the fact that only one particular region of Cape Town was studied, or it may be a chance finding. However, as we found no significant differences between males and females in the factors studied (and, in any case, sex ratios are probably not relevant to the purpose of the study, which is the phenomenology of depression), it would seem reasonable to regard the high proportion of females as probably not very noteworthy.

The absence of other forms of neurosis in this study bears out the contention that depression is "the neurotic disorder of old age" (Kay & Bergmann, 1980). None of the depressed respondents was receiving antidepressant medication, but significantly more were on tranquillisers and vitamins than were the controls. It would appear that their emotional distress had been recognised by clinicians, but not diagnosed as depression. This may be because anxiety and agitation (worry, nervous tension and irritability) were found in over 70% of depressed cases on the PSE. In addition, tension pain was present in significantly more of the depressed respondents, and this may also have impaired the recognition of depression by clinicians.

However, on direct enquiry, as the PSE requires, depressed mood was present in 94.6% and observed depression in almost 80% of the respondents given a PSE/clinical diagnosis of depression. Thus, if one asks about depression and carefully examines for it, a clear depressive affect may well be found; these PSE items in combination serve as an excellent screen for depression.

With particular reference to the use of the PSE and CATEGO program in community surveys of depression, it is worth noting that in all cases where the program gave a tentative diagnosis of depression which was not confirmed by clinical review, the Index of Definition was low (5). In most of these, a tentative diagnosis of depression had been made by the CATEGO program, taking account of anxiety symptoms alone, and this is seen as a defect in the program. It confirms Wing's contention (1983) that CATEGO tentative diagnoses must be reviewed by taking clinical information into account. Our findings make it clear that this is particularly so in depression with a borderline Index of Definition.

With regard to the presentation of depression, although hopelessness occurred as a symptom in just over half the depressed respondents, suicidal plans (which might be expected to be associated) were present in only one case (5.3%). The low rate of suicidal intent is particularly interesting in view of the high rate of alcoholism in the males of this cohort (15%) since these are commonly associated (Gillis, 1969); only one of our alcoholic subjects was rated as depressed, and he did not express suicidal intent. Suicidal tendencies are also said to be common in depressives with hypochondriacal symptoms (Post, 1965), but, although the latter was frequent (in 26%), it was not associated with suicidal intent. A possible explanation for the lower suicidal intent is that since most of our subjects were not isolated (the majority lived in close families and the rest had considerable social support), a known important risk factor was diminished (Berkman & Syme, 1979).

Loss of libido, unlike other vegetative symptoms, was present in only one respondent (5.3%). This low prevalence may be artefactual, because the majority of respondents, being widowed or single, did not live in situations where sexual desires were likely to be stimulated or opportunities offered (Newman & Nichols, 1960). Furthermore, young raters in a community survey of elderly respondents may not have enquired about sexual desires and fantasies in any depth.

Depressive delusions were not significantly present in the depressed group; this may be because when the condition was severe enough for delusions to develop, the person had probably been admitted to hospital. Depressive delusions are likely to be very rare in a community sample, occurring only in severe clinical depression (depressive delusions occur in about 28% of depressed inpatients [Eagles, 1983]). A similar explanation probably applies also to the low frequency of depressive symptoms, such as dulled perception and loss of affect.

In this group as a whole, depressed as well as non-depressed, there was a high rate of pathological symptoms, particularly those of 'neurosis'. Tension pains, subjective anergia, tiredness, nervous tension, delayed sleep and irritability were present in between 10 and 21% of the non-depressed group and were significantly more prevalent in the depressed. Amongst the latter, the most prevalent symptom ('worry') occurred in about 80%. This high rate of 'neurotic symptoms' has been discussed by Ben-Arie *et al* (1983), but accords with other investigations on the aged, as reviewed by Simon (1980). These symptoms are found commonly in epidemiological surveys, and particularly relevantly in a study of coloured persons as a whole (Gillis *et al*, 1968), but are rarely sufficiently severe to impair functioning or to lead to a rating of psychiatric illness (Bebbington *et al*, 1980).

To some extent, however, the high rate of symptoms may reflect the aggregation of a high level of physical ill-health in this population (Nash & Meiring, 1983), decreasing opportunities and mobility associated with age, and also possibly a degree of frustration as a result of living under adverse socioeconomic circumstances for many years.

In social performance, the depressed group showed significantly more impairment in coping with household tasks, management of children and relating to acquaintances, although there was no difference in their tidiness, dress and general hygiene. What impressed the raters was the generally good physical state of all the respondents, including the depressed, and the adequacy of their nutrition (Jacobs *et al*, 1984). This was felt to be due to the care and support given by families and friends.

This study indicates that the PSE and CATEGO program are effective in detecting depression in a community survey of the elderly, particularly where the Index of Definition is above 5 and clinical information is taken into account. It is also possible that depression is often missed by clinicians because of the more obvious presentation of symptoms such as anxiety or tension pain. Furthermore, clinicians may have diagnosed depression in some cases, but have considered minor tranquillisers to be a suitable form of medication. However, a specific enquiry will bring depression to light (if present), and this should be sought for when elderly persons complain of a variety of non-specific or unexplained physical symptoms, together with increasing difficulty in coping with usual life tasks.

We should like to acknowledge the help of Professor L. S. Gillis, Miss J. Cassidy, Dr T. J. van Wyk Kotze and many other colleagues.

Appendix

PSE profiles of respondents receiving an ID of 5 and a CATEGO tentative diagnosis of depression but excluded from analysis of clinical grounds

Note: PSE item numbers and names are given. Where an item is followed by (2), the respondent scored 2 on this. In all other cases a score of 1 was obtained.

Respondent A: 1. Subjective evaluation of physical health; 10. Nervous tension; 35. Delayed sleep; 66. Visual hallucinations (clear consciousness); 120. Observed anxiety; 121. Observed depression; 131. Slowness of speech.

Respondent B: 4. Worry; 5 Tension pains; 6. Tiredness (2); 10. Nervous tension; 22. Recent loss of interest; 40. irritability (2); 120. observed anxiety.

Respondent C: 1. Subjective evaluation of physical health (2); 4. Worry; 6. Tiredness; 8. Restlessness and fidgeting; 9. Hypochondriasis; 10. Nervous tension; 11. Free-floating autonomic anxiety; 28. Social withdrawal; 35. Delayed sleep; 36. Subjective anergia and retardation; 40. Irritability (2).

Respondent D: 5. Tension pains; 6. Tiredness; 11. Free-floating autonomic anxiety; 12. Anxious foreboding with autonomic accompaniments; 17. Specific phobias; 18. Avoidance of autonomic anxiety; 111. Observed agitation; 120. Observed anxiety.

A Long-term Retrospective Follow-up Study of Patients Treated with Prophylactic Lithium Carbonate

C. PAGE, S. BENAIM and F. LAPPIN

Patients suffering from unipolar and bipolar affective illness, who began treatment with prophylactic lithium carbonate during a 5-year period, were followed up and 59 out of 101 interviewed. Most had been taking lithium for at least 13 years: 49% had a complete remission, 41% a partial but significant response, and 10% no response. No specific individual or illness factor was found to correlate with favourable outcome, and no correlation between average serum lithium level and outcome. No side-effects could be associated specifically with the long-term use of lithium, but there was a surprisingly high incidence of clinical hypothyroidism.

This paper presents the results of a long-term retrospective follow-up study of a sample of patients given lithium carbonate as prophylaxis against recurrent affective disorders. Since the first classical papers of Baastrup & Schou (1967, 1968*a*,*b*; Schou, 1968) there have been a number of similar studies, using the so-called 'mirror-image' technique to assess the efficacy of prophylactic lithium. In addition, several controlled, random-assignment, double-blind studies have clearly established the efficacy of prophylactic lithium in both unipolar and bipolar patients (Coppen *et al*, 1963, 1971; Baastrup *et al*, 1970; Prien *et al*, 1971, 1973*a*,*b*, 1974; Cundall *et al*, 1972; Persson, 1972; Mendlewicz *et al*, 1973; Stallone *et al*, 1973; Dunner *et al*, 1982; Kane *et al*, 1982; Peselow *et al*, 1982).

The limitations of this type of retrospective study have been described (Blackwell & Shepherd, 1968; Blackwell, 1969), but this particular study is the first to follow a large cohort of patients over a period of 17 years, with detailed follow-up data being established first in 1971 and then 12 years later, in 1983. Thus, useful information has been obtained regarding long-term efficacy and side-effects, despite the fact that the data could not be subjected to a rigorous 'mirror-image' analysis.

Method

The sample

The subjects were a consecutive series of 101 patients, the first to be treated with prophylactic lithium by one consultant psychiatrist working in north London; all began lithium therapy between 1966 and 1971. Prior to that time, all had suffered from several episodes of depression and/or hypomania. The criteria for defining these episodes were that specific symptoms of depressive or hypomanic mood were elicited by the clinician, which were of at least 2 weeks duration and of sufficient severity as to impair the subject's usual functioning, though not necessarily requiring admission to hospital. There were distinct intervals between these episodes when the subject's mood state was normal for at least 4 weeks.

Assessments of the patients

Initial status

A detailed examination of their hospital and clinic case notes was carried out to identify characteristics of this group at the time of initial lithium prescription. This included:

(a) demographic details (age, sex, socioeconomic and marital status, employment record);
(b) family history of physical and psychiatric illness;
(c) initial diagnosis and detailed psychiatric history prior to commencing lithium treatment, including age of onset, length and pattern of illness, previous treatment, characteristics of illness including the presence or absence of specific symptoms, frequency of relapses, suicide attempts.

Follow-up status

In 1971, the entire cohort of patients who had been taking lithium for up to 5 years was reviewed (Benaim & Lappin, 1973). They were assigned to one of three outcome groups, depending on whether their response to lithium was complete, partial or insignificant. These outcome groups were defined as follows:

(a) complete response, i.e. there had been no episodes of hypomania or depression requiring treatment whilst the patient was taking lithium;
(b) partial response, i.e. some episodes of illness occurred whilst the patient was taking lithium, but these were less often and produced less handicap (in terms of need for additional medication, admission to hospital, duration of episode, time away from work) than those prior to lithium treatment;
(c) insignificant response, i.e. there was no detectable change in frequency or severity of relapses after lithium treatment was begun.

In 1983, attempts were made to trace these patients again via out-patient clinics, general practitioners, family practitioner committees and informal sources. All were asked to attend for interview, with the option of being interviewed in their home if unable to travel. The interview included collection of the following data: demographic details, psychiatric and physical morbidity since beginning lithium treatment, details of lithium therapy (average dose, length of time for which the drug was taken, individual patterns of taking treatment, compliance, reasons for discontinuation), employment history, marital history and social functioning since commencing treatment.

In order to assess their mental state at the time of interview, the ninth edition of the Present State Examination (PSE) was administered (Wing *et al*, 1974).

Analysis

The course of each individual's illness whilst on lithium was thus examined in terms of episodes of depression or hypomania, number of admissions, severity of the recorded episodes, frequency of episodes, suicide attempts and ability to function adequately at work and at home. A comparison was then made with the pre-lithium data for each individual and with the data obtained in 1971, the latter to assess the stability of the response. These comparisons were analysed using the chi-squared test.

Results

Of the 101 patients, 59 were interviewed in 1983: 20 were dead (detailed information regarding this group was sought from case notes, general practitioners and relatives), two were living abroad, four refused to be interviewed and 16 were never traced.

Characteristic of the initial sample

Sociodemographic details

The original group comprised 47 men and 54 women, their ages ranging from 19 to 75 years, the mean age at commencing lithium treatment being 45 years. A total of 74 were married, nine divorced, 15 single and three widowed. According to the Registrar General's classification, 22% were social class I, 49% social class II, 20% social class III non-manual, 7% social class III manual and 2% social class IV.

Diagnosis

At the time of starting lithium, 35 patients were classed by one of the authors (S. B.) as having unipolar affective disorder, 65 bipolar affective disorder and one a schizo-affective disorder.

Family history of psychiatric illness

A positive family history of bipolar illness was found in 61 subjects, and in all but one of these, their own diagnosis was also that of bipolar illness. There was a family history of unipolar illness in 46, which was evenly distributed amongst subjects with both diagnoses. There was a family history of completed suicide in 18, of which 14 were bipolar subjects. Nine had a family history of alcoholism; all of these were bipolar subjects.

Age of onset of illness

In 30, the age of onset of illness was less than 25 years, in 34 it was between 26 and 35 years, in 22 it was between 36 and 45 years, and in 15 it was over 45 years. There was no significant difference in age of onset of illness between those subjects with bipolar and those with unipolar disorders.

Characteristics of illness prior to lithium

The characteristics of illness before treatment with lithium included on average 8.5 depressive episodes (range 0–80), 3.8 admissions for depression (range 0–30), 2.7 hypomanic episodes (range 0–16), 2.1 admission for hypomania (range 0–9). The average frequency of episodes was 19 months.

The length of illness prior to lithium treatment varied from 1 month to 30 years, with a mean of 5 years. The frequency of occurrence of episodes was no different between unipolar and bipolar subjects.

Analysis of preliminary data

All the preliminary data were examined to see whether the original population could be defined by distinct subgroups, clustering in terms of sex, age of onset of illness, symptoms or family history. Using the chi-squared test to compare subgroups, it was not possible to demonstrate any significant clusters.

Follow-up data (1983)

Patients not available

No follow-up data were available for 22 patients. This group was not significantly different from the remainder of the original population in terms of any initial variables, as determined from their case notes.

Patients who had died

Twenty patients had died by 1983. The causes of death were: suicide (6), cancer (5), myocardial infarction (4), accident (2), cerebrovascular accident (1), respiratory failure (1) and pulmonary embolus (1). At the time of death, eight of these were known to still be taking lithium. In comparing the 20 dead subjects with the rest of the original population, there was no major differentiating characteristic of statistical significance. All six who committed suicide had been diagnosed as having bipolar illness, in each case characterised by severe depressions which prevented them from working or functioning socially; five had shown a partial response to lithium and one had shown no response. The average age at time of death was 47 years (range 30–56).

Patients who were interviewed

A total of 59 patients were re-interviewed in 1983. On examination of their mental state, including use of the PSE, none of these were found to have clinically significant psychiatric signs or symptoms, either at the time of interview or in the preceding 4 weeks. It was therefore presumed that the data which they provided at those interviews were valid.

Lithium usage

Their average age at starting lithium was 45 years (range 19–75). Figure 1 shows the length of time for which these patients had regularly taken lithium; most had taken it for more than 13 years.

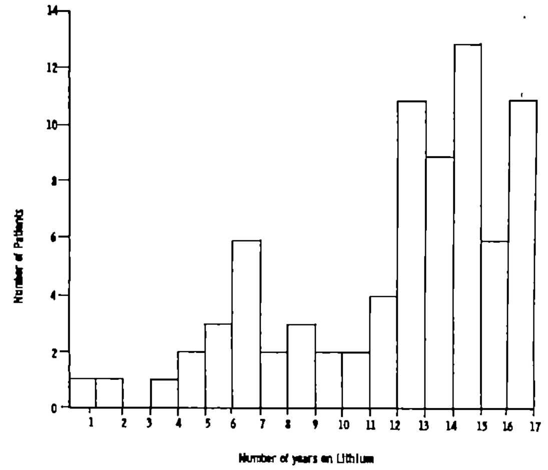

FIG. 1. Length of time for which patients had taken lithium (total = 957 patient-years on lithium).

The mean daily dose was 800 mg (range 250–1600 mg), mostly as single daily dose preparations. The mean recorded serum level, approximately 12 h post-dose, was 0.7 mmol/litre (range 0.3–1.2 mmol/litre). Since lithium was first prescribed for them, 61% had taken the drug continuously. The reasons given by the others for stopping lithium were: unwillingness to take long-term treatment (12), unacceptable side-effects (11), the treatment considered ineffective by the doctor (4), concomitant physical illness (3) and in order to become pregnant (1). Twenty-nine of the total 31 who stopped taking lithium suffered relapses, and 19 subsequently recommenced their treatment. Two subjects (both with a unipolar illness) have remained free of recurrence since stopping lithium and have now been well, without medication, for over 6 years.

Outcome

As described above, the subjects were all assigned to one of three outcome groups, both in 1971 and in 1983. In 1971, (when 101 subjects were included), 48% had shown a complete response, 42% a partial response and 10% an insignificant response. In 1983, (when 59 subjects were re-examined), 49% had shown a complete, 41% a partial and 10% an insignificant response. In the 12 years since these patients had been reviewed, the proportions in each group had not changed and there was no movement between outcome groups of the 59 patients followed up in 1983.

Having categorised the patients in terms of their response to lithium, all the preliminary and follow-up data were examined to see whether there were any variables which correlated with outcome (using the chi-squared test). No association was found between outcome and any of the variables examined, which included: age, sex, family history, age of onset of illness, diagnosis, previous treatment, previous physical history, nature and severity of their pre-lithium illness, dose of lithium, average serum level and concurrent treatment or side-effects.

During the period of lithium treatment, the marital and socioeconomic status of these patients had remained similar to that pre-lithium, but a higher proportion were able to work fulltime (36 compared with 12 before lithium).

At the same time of follow-up, four subjects were found to be living in institutions (one in a long-stay ward of a psychiatric hospital, three in old people's homes).

Other treatment

Additional treatment was given concurrently to 43 (73%) of these patients at some point during their lithium treatment. In the case of patients who had no further episodes of affective illness after starting lithium, the additional treatment given was either hypnotic drugs or psychotherapy. The percentages receiving other forms of treatment, compared with the pre-lithium figures, are shown in Table I.

Side-effects

The side-effects recorded in the case notes, or reported on detailed questioning at interview of the 59 patients, were as follows: tremor (23 subjects), subjective memory loss (23), weight gain (21), polyuria or polydipsia (21), loss of creativity (11), diarrhoea (10), hypothyroidism (10), goitre (7), nausea (5), impotence (5), gastric pain (4) and psoriasis (4). Hypothyroidism was diagnosed biochemically by routine measurement of plasma T_3 and T_4 and of TSH. Eleven subjects stopped taking lithium because of side-effects. None of the 59 patients seen in 1983 had any known renal disease and no other side-effects which might be specifically associated with prolonged use of lithium were detected.

TABLE I
Percentages of patients receiving other forms of treatment

Other treatment given	*Prior to lithium treatment (mean 5 years)*	*Concurrent with lithium treatment (mean 11 years)*	*P value*
Tricyclic antidepressants	88	61	<0.01
Monoamine oxidase inhibitors	43	19	<0.01
Barbiturates	69	12	<0.01
Benzodiazepines	70	47	<0.01
Phenothiazines	62	34	<0.01
Electroconvulsive therapy	58	12	<0.01
	(4–180 treatments)	(3–12 treatments)	<0.01
Psychotherapy/analysis	31	20	0.1

Pregnancies

One woman became pregnant whilst taking lithium, and this pregnancy was terminated for social reasons. One other woman stopped lithium in order to become pregnant; she became hypomanic after the birth, and lithium treatment was re-instituted.

There were no reports of infertility amongst these subjects, although their age and illness meant that most were not wishing to have more children. The wives of four of the male subjects became pregnant; there were no reports of physical or psychological problems in these children.

Discussion

This study presents retrospective data from a large cohort of patients taking prophylactic lithium over a period of up to 17 years. Potential bias was introduced, in that 22 patients were either not traced or would not be interviewed. It is possible that these subjects were those in whom lithium had not produced a favourable response, and that they were therefore unwilling to cooperate with the study. This group of patients is also unusual in the marked bias towards social classes I and II, which is thought to be due to the inclusion of patients referred from outside London and even from other countries, at a time when lithium was not widely used or available. These latter patients were predominantly from the higher social classes.

Despite these methodological shortcomings, the results obtained do reveal several interesting points. First, 50% of patients showed a complete remission whilst on prophylactic lithium, 40% showed a partial but significant response and 10% a negligible response. This response was true of both unipolar and bipolar patients, and the prophylactic effect of lithium carbonate did not diminish with time in the patients who showed a good response.

The percentage of patients who show no apparent response to prophylactic lithium varies considerably in published studies. However, all studies agree that there is a significant proportion of both unipolar and bipolar patients who will relapse whilst taking lithium carbonate. This study has followed subjects over a long period of time, and has indicated that the subjects can be categorised according to response within the first 5 years of treatment. On examining the same subjects 12 years later, none had moved from one outcome group to another. It has previously been suggested by Dunner & Fieve (1974) that if patients are followed for long enough, they will all ultimately have a further affective episode, but this study did not confirm that hypothesis.

Secondly, in the bipolar group of patients, lithium was equally effective in preventing hypomanic and depressive episodes. This has been a subject of debate for some years, since Prien *et al* (1971, 1973*a*,*b*, 1974) found that lithium had a greater effect in preventing the manic phase of illness rather than the depressive phase. However, Baastrup *et al* (1970) and Coppen *et al* (1963) have found essentially similar prophylactic effects against the manic and depressive phases in their bipolar patients, and the results of this study, with a larger number of patients, confirm that finding.

Thirdly, these results do not show that a positive family history of bipolar illness indicates a more favourable response to prophylactic lithium; nor were we able to isolate any other specific factor which was correlated significantly with outcome. This conflicts with the strong correlation found by Mendlewicz *et al* (1973) between positive family history of bipolar illness and good response to prophylactic treatment. However, using a life-table method of analysis on a cohort of 120 patients, Dunner *et al* (1976*a*) found no association between negative family history and failure of lithium prophylaxis. In addition, on analysis of the relationship between sex, age at treatment, diagnosis, number of previous episodes, age of onset of illness and outcome of treatment, they concluded that there was no significant association between any of these factors and outcome. Our long-term study substantiated this evidence and also demonstrated no correlation between eventual outcome and certain other factors, including previous physical history, previous treatment, severity of illness before treatment, symptoms before treatment, dose, serum level and occurrence of side-effects.

Fourthly, only three of our subjects could be defined as 'rapid cyclers' (four or more affective episodes per year), and all of these seemed to derive considerable benefit from prophylactic lithium. Dunner & Fieve (1974) described this subgroup of manic-depressive patients and noted that they seemed not to respond to prophylactic lithium. However, in a later paper, Dunner *et al* (1976*b*) re-analysed the data from their sample of 'rapid cyclers' and concluded that lithium carbonate was effective in preventing hypomanic episodes in these patients.

Fifthly, the mean serum level, measured 12 h post-dose, was 0.7 mmol/litre in all three outcome groups, with no correlation between mean serum level and outcome. The guidelines concerning desirable plasma lithium levels for prophylaxis are still conflicting. A number of studies have indicated a higher rate of relapse among subgroups of patients maintained with average serum levels below 0.4 mmol/litre (Hullin, 1980) and 0.8 mmol/litre (Prien & Caffey, 1976). Recently, however, Peselow *et al* (1982) examined a large cohort of patients maintained on prophylactic lithium alone and found that they were unable to demonstrate a minimum level of lithium below which prophylaxis against depression is ineffective. Sashidaran *et al* (1982) followed a cohort of 53 patients on lithium therapy and retrospectively detailed their serum level and mental state over a period of 3 years. They found that those who did not relapse during the trial had spent significantly less time with serum levels over 0.9 mmol/litre than had those who relapsed.

Finally, the side-effects found in our subjects have all been previously well documented. There was a surprisingly high incidence of clinical hypothyroidism, and further work is in progress to examine this group in more detail. We were not able to demonstrate any side-effects specifically associated with long-term lithium treatment, but in view of the association of tardive dyskinesia and long-term neuroleptic treatment, it is essential to continue to monitor closely those patients who have taken lithium for extended periods, in case of similar developments.

The Effect of Carbamazepine and Lithium on Remission from Affective Illness

S. E. WATKINS, K. CALLENDER, D. R. THOMAS, S. F. TIDMARSH and D. M. SHAW

Times in remission from affective illness were prolonged during treatment with lithium carbonate and carbamazepine, but lithium was the more effective. Similar global scores for the two drugs suggested that other factors may determine their acceptability.

The salts of lithium are used for the treatment of recurrent affective disorders to reduce the frequency and severity of illness, but their low therapeutic index and tendency to induce side- and toxic effects in some individuals have led to the search for substances with the same therapeutic properties and fewer disadvantages. Recent studies have suggested that carbamazepine may be an alternative to lithium in this context (Takezabi & Hanaoka, 1971; Okuma *et al*, 1973, Inanaga *et al*, 1981; Ballenger & Post, 1980; Kishimoto *et al*, 1983; Nolen, 1983), and a pilot comparison of these two drugs is reported here.

Method

The protocol was for a randomised double-blind retrospective/prospective study of the mood-stabilising properties of lithium and carbamazepine in respect of time in remission from affective illness. Many of the patients knew about and were aware of the early symptoms of relapse in their case, and our normal practice is to give them the option of taking antidepressant drugs temporarily at these times. This option was retained for ethical reasons, and for those patients who did not fulfil the criteria of full relapse (i.e. a Hamilton depression score (1967) of less than 10) during this period, the presence of this attenuated and treated minor episode was not counted as interrupting time in remission. Thus, the trial is really that of the effect of lithium and carbamazepine on this mode of management of affective illness. This design might have biased the results, but the option to take antidepressants temporarily was taken up by 61% on lithium and 63% on carbamazepine.

Patients were accepted into the trial if: (1) they were experiencing mania or a major depressive episode, using the criteria of DSM-III, (2) there was a well-defined recorded previous episode, and a known time of recovery from which the time in remission without the benefit of a prophylactic could be estimated. The previous period in remission had not been 'covered' by putative prophylactic drugs (including tricyclic or MAOIs) either because the patient was coming *de novo* to this form of therapy or, thinking he no longer needed it, had defected from such treatment. Of the 52 accepted for the trial, only seven were withdrawn for the combined reasons of having moved away or non-compliance.

These criteria also applied for subsequent episodes of illness. Remission was timed from the beginning of therapy with lithium or carbamazepine, which was usually at the end of the second week after achieving scores of 10 or less on the Montgomery–Åsberg (1979) or 3 or less on the Modified Manic State scales (Blackburn *et al*, 1977). If relapse occurred within 3 weeks of starting lithium or carbamazepine, that person was taken out of the trial; this applied to only two patients.

Side-effects were rated non-blindly and globally by the prescribing medical staff, using the scale of mild, moderate and severe. Only volunteered complaints which were rated as moderate or severe were counted, and these occurred in six of the 18 on lithium and three of the 19 on carbamazepine (χ^2, NS).

The global ratings for patients (self-rating) and doctors had three choices: the same or worse/improved/completely well. The doctors completed their rating at the end of the trial period for that patient; all subjects in the analysis completed and returned their self-rating scales. The form was sent by post to avoid—as far as possible—the tendency of the patient to want to please the staff.

All patients underwent a physical examination and the following tests: haemoglobin, red cell count, white cell count, urea, electrolytes, creatinine clearance, urine for protein/casts, thyroid profile, serological tests to exclude syphilis, skull/chest X-ray, ECG (and liver function tests in some). None with evidence of organic illness was accepted. All the patients included gave informed consent.

The drugs used were tablets of lithium carbonate (400 mg) and carbamazepine (200 mg), with appropriate placebo preparations for each. The patients were given an active drug and the opposite placebo (lithium [or its placebo] in split dosage (*b.i.d.*) and carbamazepine [or its placebo] at night). Active and placebo drugs were increased in parallel. Change in initial dosage was made every 5–7 days until plasma levels of 0.4–0.9 mmol/litre for lithium and 5–12 μg/ml for carbamazepine were reached in samples taken 12 ± 0.5 h after the previous night's dose.

Antimanic or antidepressant drugs were given as required for a relapse. Lithium was discontinued if the episode was manic and haloperidol was to be used; otherwise, both drugs were carried on through the illness.

The mean times the patients were observed are given in Table I. No patients were admitted to the trial from 6 months before it was due to terminate, and no data were included unless the period of observation of the patient had exceeded the previous cycle length (time between onset or index and preceding illness). Since the therapies on trial were started at the beginning of the period of remission, the

40–49	4	4
50–59	5	4
60+	6	5

comparison used was that of the time in remission rather than the length of cycle.

Patients were assessed in the index illness and then weekly for 4 weeks for psychometry and blood levels (for some patients, a fifth drug assay was included). They were then reassessed every 2 months for repeat drug assays, psychometry and white cell count. At 6-month intervals, the thyroid profile, blood urea and creatinine clearance tests were repeated. Subjects were asked to make additional visits if they experienced mood changes lasting more than 3 days or had problems with their drugs.

The protocol excluded patients with white cell counts of 3.5×10^9/litre and any whose counts fell below this level, but this did not occur in the sample studied.

The medical staff who rated the patients were separate from those who prescribed, checked blood levels, altered dosage, and monitored laboratory tests and side-effects. These side-effect scores were assessed non-blindly by the prescribing doctors. The other ratings were made blindly, and the raters limited their enquiries to this task. The maintenance of blindness of the ratings was tested by a guess score at the end of the trial. There were 23 correct guesses out of 38 (NS), which suggests that double-blind conditions had been maintained, at least as far as the raters were concerned.

However, the same did not apply to the patients. Some were able to 'break the code', probably because of familiarity with the side-effects of lithium. This seemed inevitable in a prolonged trial. Despite the correct guesses by some, when it became clear that patients were working out their drug therapies correctly, they were asked not to, and apparently did not reveal this information to the raters. Allocation to the two treatments was by a series of random numbers.

If two episodes occurred, the trial was terminated for that patient. A total of 52 patients were selected for the trial and agreed to participate, of which 37 completed. The reasons for losses and additional exclusions from the trial were: intolerance to drug during the start of therapy (one on lithium and one on carbamazepine), one case of hypothyroidism during therapy (lithium), relapse in first 3 weeks of therapy (two cases). There were seven cases of non-compliance or of moving away, making a total of 15 patients accepted for the trial but not completing it.

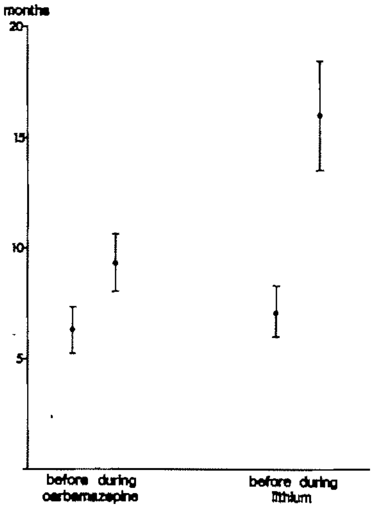

FIG 1 Times in remission (means ± s.e.). Carbamazepine: $P<0.001$; lithium: $P<0.001$.

Results

Table I gives the ages, sex, diagnoses and average times of observation in the patients who completed the trial. The mean times in remission before and after each drug are illustrated in Figure 1. The mean time (±s.e.) before starting lithium carbonate was 7.1 ± 1.1 months and was 16.0 ± 2.4 while taking this drug. The mean (±s.e.) for carbamazepine was 6.3 ± 1.0 before the 9.4 ± 1.3 afterwards. Both differences were significant ($P<0.001$ in each case, t-test for paired observations). The 'additional time' in

There were no significant differences between the drugs.

remission while on lithium was 9.3 ± 2.0 months (mean ± s.e.) as compared to an extra 3.3 ± 0.8 months on carbamazepine, so that lithium was significantly the better drug ($P < 0.001$, t-test). A shorter time of observation would be expected if patients relapsed more rapidly with carbamazepine, and this was observed.

Discussion

From the now considerable work on lithium and from the view that affective illnesses tend to occur more frequently with age (Angst *et al*, 1969; Grof *et al*, 1970), it is to be anticipated that cycle length and time in remission will decrease with succeeding episodes. In neither group did this occur, and in fact time in remission was increased. Lithium, with or without additional medication for minor deterioration, was significantly superior in this respect to carbamazepine.

Our conclusion from this preliminary study has confirmed the observation that lithium significantly lengthens time in remission, while the effect of carbamazepine is more modest. However, it is an alternative to be considered in patients who have been intolerant of lithium or whose illness does not respond to this drug. The similarity of global scores may also point to other factors which may enter into the tolerance to and acceptability of the two drugs, such as the particular pattern of even mild side-effects, e.g. tremor and polyuria, which it was felt was the means by which patients 'broke the code'.

The reason that this particular design was chosen was partly because in a retrospective/prospective study it is difficult sometimes to pinpoint time of onset of a previous illness. Another reason was that prophylactic therapy cannot be started with carbamazepine during treatment if this consists of electroconvulsive therapy (ECT). As it is our practice to give ECT, wait to see if recovery is complete, then give one or two more if the patient is relapsing, an individual patient may be 2 or 3 weeks into remission before a prophylactic drug is started. The most appropriate comparative measure is therefore remission time in patients in whom carbamazepine or lithium is started 2 or 3 weeks into this period.

Also, one of the criteria for entry was a clearly defined and recorded time of recovery from a previous episode. Thus, it was possible to calculate reasonably accurate times in remission and to determine from the recent and therefore accessible history the time of relapse into the current episode.

The design might be criticised on the grounds that additional therapy was given for relapses and that blindness to therapy on the part of the patients was lost. The option to use additional therapy for episodes of illness was retained for ethical reasons and was taken by similar proportions of patients in the two groups. As regards breaking of the code by the patient, in our view this is inevitable in a long trial where one of the drugs — in this case lithium — has distinctive identifying side-effects.

Suicide and Parasuicide Among Further Education Students in Edinburgh

S. D. PLATT

During the period 1979–1982 the incidence of suicide and parasuicide for students aged 15–24 years was found to be lower than that of others of the same age in Edinburgh. A comparison of student parasuicides with matched non-student parasuicides shows similar parasuicide repetition rates, but some differences in respect of precipitants (twice as many students reporting no major event prior to the episode), agent of poisoning (analgesics more commonly used by students; hypnotics, tranquillisers and barbiturates, by controls), and social and clinical characteristics (a greater proportion of controls reporting parasuicide in the family, a criminal record and being the victim of violence).

Much published research appears to confirm the popular view that students are excessively prone to suicide. Among male students at Cambridge, Oxford and University College, London, in the post-war years, suicide rates were significantly in excess of those expected for the relevant age group (Carpenter, 1959). Even the reduced rate of 10 per 100 000 among Oxford University males during 1966–1976 (Hawton *et al*, 1978) was twice as high as the rate for males aged 15–24 in England and Wales at the mid-point in the study (1971). However, in the only study of its kind, Hawton *et al* (1978) reported lower parasuicide inception rates among students compared to non-students.

This study reports the results of an investigation into the incidence of suicide and parasuicide among students in further education in Edinburgh over the period 31 January 1979 to 31 December 1982. Clinical and sociodemographic characteristics of student parasuicides are compared with those in a matched sample of non-student (control) parasuicides. Results are discussed in the light of findings reported in previous studies.

Method

Suicide

Using information provided by the General Register Office (Scotland) a count was made of all 'suicides' (ICD codes E950–E959) or 'undetermined' (E980–E989) deaths among students aged 15 years and over and usually resident in the city of Edinburgh. 'Undetermined' deaths are included because these tend to resemble suicides more closely than accidents (Holding & Barraclough, 1978). Three major problems arise when using this data source. Firstly, the deceased person may have been in the secondary, rather than tertiary, education sector. Unfortunately, it was not possible to ascertain the name of the institution where the person was a student, nor details of year of study, course or degree. Secondly, the person may have been studying outside Edinburgh but have committed suicide in the city. If his/her 'usual address' was held by GRO to be the parental home in Edinburgh, then this death would be included in the sample. Thirdly, any Edinburgh student committing suicide outside Scotland was not recorded. (However, deaths of Edinburgh residents occurring outside Edinburgh, but elsewhere within Scotland, are included.) While it is not possible to calculate precisely the net effect of these possible errors, they probably result in an underestimate of the frequency of student suicide in the city.

Parasuicide

Parasuicide is defined as 'a non-fatal act in which an individual deliberately causes self-injury or ingests a substance in excess of any prescribed or generally recognised therapeutic dosage' (Kreitman, 1977). This definition excludes intoxication with alcohol alone. Information was collected on all identified cases of parasuicide involving students currently resident in Edinburgh and registered at an institution of further education in the city, who were admitted to the Regional Poisoning Treatment Centre (RPTC) at the city's Royal Infirmary during the study years. Over 90% of all adult patients admitted to hospital from an Edinburgh address for treatment of self-poisoning are received by the RPTC (Holding *et al*, 1977). All referrals are admitted regardless of the severity of their physical condition (Matthew *et al*, 1969), but some must be missed. The RPTC also receives cases of self-injury, although these are less systematically referred than the cases of self-poisoning and are therefore likely to be a less representative sample of the total number of such cases. Kennedy & Kreitman (1973) have shown that parasuicides admitted to the RPTC are representative of all medically treated parasuicides. Mindful that an unknown number of student parasuicides will not have been included in this hospital sample, I made enquiries at each institute of further

education in the city. However, very few cases came to light; all were already included in the sample.

A control group of non-student parasuicides was drawn from the RPTC archival data set. Each parasuicide was matched with the next parasuicide admitted to the RPTC who fulfilled the following criteria: resident in Edinburgh, not a student, same gender and same age (within one year). Comparisons between students and non-students were made on all sociodemographic, clinical, treatment and social problem variables routinely recorded for RPTC admissions. The significance of differences between groups was assessed by means of the McNemar Test (Siegel, 1956). In addition, information was gathered on the total number of admissions in the two groups over the study period. Finally, an attempt was made to compare groups on the presence and type of any major life event preceding the episode. Information was taken from letters written by the RPTC psychiatrist to the person's general practitioner on his/her discharge from the ward.

Epidemiology of suicide and parasuicide among students

The calculation of suicide and parasuicide rates for students is complicated by three problems. Firstly, those studying in Edinburgh are only definitely resident in the town for approximately 30 weeks of the year; during the vacations they may be living elsewhere. Secondly, students show a wide age range. A third problem concerns the amount of time spent weekly in connection with studies at a further education institution, which varies from a few hours part-time on secondment to a full-time degree course. For these reasons, the numerator is restricted to students studying full-time, aged 15–24 years and whose suicide or parasuicide occurred during term-time. An additional difficulty lies in the fact that students are known to be unrepresentative of the general population of the same age in respect of social class distribution. Unfortunately, it has not proved possible to obtain a social class breakdown of the student population in Edinburgh, and information on the social class position of student suicides and parasuicides is also unavailable.

On the basis of estimates provided by the further education institutions and by the Education Department of the Scottish Office, the numbers of full-time students in Edinburgh aged 15–24 years were calculated for each year of the survey. Denominators for non-students were obtained by subtracting the estimated number of students from the estimated total for the whole age group (as provided by GRO). Because of the small numbers involved, only two mean suicide rates (one for students and one for controls) were calculated for the whole period, the total number of term-time suicides (and undetermined deaths) over the 4 years being divided by the relevant population estimates for 1981, the resultant fraction being expressed as a rate per 100 000. For parasuicide, a rate per 100 000 was calculated for each year based on the unduplicated count of persons aged 15–24 admitted to the RPTC during the 30 weeks of term-time (numerator) and the appropriate population estimates (denominator). The four rates were then averaged to give a mean parasuicide rate for the whole period. Parasuicide rates were calculated separately for males and females, and separately for students and non-students. It is important to note that both suicide and parasuicide rates cover the same 30 week periods (term-time) for students and non-students alike.

Significance tests are not provided or required when assessing differences between student and non-student rates. Numbers of suicides and parasuicides are either total counts or estimates of total counts, and no attempt is made to generalise from Edinburgh's experience to the rest of Great Britain.

Results

Suicide and undetermined death

Between 1979 and 1982 there were three student suicides in Edinburgh: a female, single, aged 21, died by carbon monoxide poisoning; a male, divorced, aged 38, died by jumping (this death occurred during the vacation); a male, single, aged 19, died by hanging; and one 'undetermined' death: a male, single, aged 18, who died by falling. None had a recorded admission to the RPTC. The mean 4-year suicide rate during term-time for the 15–24 year age group (omitting the male aged 38) was 2.6 ($n=2$) per 100 000 among students and 8.8 ($n=22$) among non-students. The mean rate for suicide and undetermined deaths combined was 3.8 ($n=3$) and 11.6 ($n=29$), respectively. Thus, students appear to have been less at risk of suicide and undetermined death than their non-student peers, at least during this 4-year period.

Parasuicide

During 1979–1982 91 students (27 male, 64 female) were admitted to the RPTC following an episode of deliberate self-harm. The mean age for males was 21.7 years (s.d. 4.0; range 17–34) and for females 20.7 years (s.d. 4.3; range 16–42).

Table I shows, separately for each year, the numbers of student and non-student parasuicides (on a term-time only basis) in the 15–24 age group, together with population estimates. Throughout the period, parasuicide was less frequent among students. Taking the mean 4-year rates, the relative risks were 1:4:2 for men and 1:2:4 for women.

While direct control for the likely skewed social class distribution among students has not been possible (see above), an indirect assessment of its confounding effect can be made, at least for males. During the study period, parasuicide rates among economically active 16–24-year-old males in Edinburgh ranged from an average of 110 per 100 000 in social classes I and II, to 537 in class V (calculated over a 30-week period). Thus the rate among professional men is double the rate of their student age peers. We can reasonably conclude that Edinburgh students have a lower parasuicide rate than other people of the same age and social class.

TABLE II

Distribution of student parasuicide by month of admission

Month	*Observed*	*Expected*[1]
January	12	8.3
February	8	7.5
March	10	8.8
April	6	6.6
May	9	8.2
June	4	7.6
July	3	7.2
August	3	9.3
September	5	7.8
October	15	6.2
November	9	7.5
December	7	6.0
	91	91.0

1. Based on the distribution of non-student admissions, 1979–1982
$\chi^2 = 24.4$, d.f. = 11, $P < 0.02$

The actual distribution of the 91 student parasuicides by month of admission was significantly different to the expected distribution based on non-student admissions over the study period ($\chi^2 = 24.4$, d.f. = 11, $P < 0.02$). The relevant data are provided in Table II. Two-thirds of admissions occurred during the period October to March (15 admissions recorded in October alone) and only one-third during the rest of the year (just four in June when most examinations are taken).

Parasuicide repetition was assessed among the 91 student parasuicides and their matched controls. Table III shows that nine persons in each group were readmitted to the RPTC. Students were thus no more likely to be readmitted than their matched controls. The total number of admissions was 113 among students (five persons admitted twice, two admitted four times, one admitted six times and one admitted seven times), and 104 among controls (six admitted twice, two admitted three times, one admitted four times).

Table IV lists the social and clinical variables on which significant differences ($P < 0.05$) between students and controls were found. More students were unmarried and living outside the family; they were also more likely to use non-prescribed drugs. A greater proportion of controls had been the victims of violence, reported an episode of parasuicides by a near relative, lived in overcrowded conditions and had a criminal record. Differences on a further 21 variables (listed in Table IV) did not reach statistical significance.

The most common method of parasuicide was self-poisoning, either alone (86 controls, 83 students) or in conjunction with self-injury (two controls and two students). Analgesics were used by more students ($n = 36$) than controls ($n = 22$); on the other hand, tranquillisers, hypnotics and barbiturates were more commonly taken by controls (29) than by students (9).

An analysis of major immediate precipitants reveals that nearly twice as many students (33) as controls (17) reported no precipitant, while many more controls (55) than students (35) referred to interpersonal problems. Academic difficulties were noted in only 18 cases (and in eight of these interpersonal problems were also present).

TABLE III

Readmission to RPTC during study period: students versus controls

		Students	
		Readmitted	*Not readmitted*

Civil state		
Not married/cohabiting	62	85
Source of drugs		
Non-prescribed	18	36
Present household		
Not living with family	28	58
Violence		
Victim of excessive force in past 5 years	24	3
Episode of parasuicide		
By near relative	22	8
Overcrowding		
Yes	10	0
Criminal record		
In prison or conviction	18	5

*McNemar test, $P < 0.05$: n of pairs differs for each variable because of missing data.

No significant differences between groups were found in respect of agent of referral; type of admission; coma level; psychiatric diagnosis; personality diagnosis; alcoholism; alcohol at time of act; previous in-patient and out-patient psychiatric treatment; previous parasuicide; permanent separation from mother or father before age 15; use of excessive force in past 5 years; psychiatric treatment received by family member; completed suicide by near relative; serious debts; police proceedings threatened; psychiatric or social work aftercare recommended; habitual misuse of drugs.

Discussion

Contrary to the findings of previous studies, this investigation has revealed a lower frequency of suicide in the student population than among non-student age peers. It is possible that the Edinburgh rate is artificially low due to inadequacies in case identification procedures. However, the same limitation to deaths occurring in the city was also a feature of the Oxbridge surveys (Parnell, 1951; Rook, 1959; Hawton *et al*, 1978). Likewise, the inability to adjust for possible social class differences between student and non-student populations is common to both the Edinburgh and Oxbridge surveys. The discrepancy between this and previous studies is unlikely to be due to a secular trend towards lower suicide rates among students, since there has been a notable increase in suicide rates among adolescents and young adults over the past decade (McClure, 1984). Furthermore, an examination of suicide among students in Edinburgh over a 14-year-period (1968–1982) shows a tendency towards more deaths in the latter 7 years ($n=9$) than during the first half of the period ($n=3$). An alternative explanation for the findings might derive from the wide definition of 'student' employed in the present study. It may be that suicide risk is higher among university students compared to those studying in polytechnics, colleges of further education and teacher-training colleges. It was not possible to compute suicide (or parasuicide) rates according to the type of further education institution. However, even if both the term-time suicides which occurred during the period 1979–1982 were committed by university students, the mean suicide rate among such students would be 4.5 per 100 000, still considerably below previously reported rates.

The frequency of parasuicide was found to be lower among further education students in Edinburgh than among the rest of the 15–24 age group. Hawton *et al* (1978) reported a similar finding in Oxford in the 1970s, but were unable to control for social class variables. Indirect evidence suggests that the lower rate among students in Edinburgh was independent of any social class effect.

The matched-pairs analysis revealed that among those reporting some major precipitant of the parasuicidal episode, the majority of both groups cited interpersonal problems (argument, fight, conflict, actual or threatened termination of relationship), most commonly with a partner. Only eighteen students referred to academic difficulties, and in eight of these cases interpersonal problems were also present. The concentration of admissions at the beginning of the academic year (October, November) and their comparative rarity at the time of examinations (June) provides further evidence of the importance of social, rather than academic, factors in parasuicide among students. A similar conclusion was reached by Bernard & Bernard (1982). As Schwartz & Reifler (1980) suggested, membership in the young adult group (where social and family problems are commonplace) may be more important in understanding suicidal behaviour among college students than anything peculiar to the status of student. Investigations among school-age parasuicides has also demonstrated the relative insignificance of the school environment and its potential stresses in accounting for the child's behaviour (Kerfoot, 1979; Lumsden Walker, 1980).

A greater number of controls reported the occurrence of a major life event prior to parasuicide, a finding which might suggest more mental health problems among the students. However, there was no significant difference overall in the proportion of the two groups given a psychiatric or personality diagnosis. The finding could be an artefact of different reporting styles, including more denial of problems among the students, and to the limitations of the psychiatric discharge letters as a source of information on the topic. Nevertheless, it remains a possible marker of unidentified psychiatric morbidity in the student group. The finding of greater use of non-prescribed drugs (particularly analgesics) among students suggests that this group is less impulsive in planning the parasuicide and therefore perhaps also has a higher level of suicidal intent than their age peers. However, no data are available to confirm this suggestion, which is contrary to the finding by Hawton *et al* (1978) that student parasuicides are no more serious than others in their degree of suicidal intent. Whatever the 'seriousness' of the original parasuicide, the parasuicide repetition rate was shown to be identical in the two groups.

A final comment concerns the findings on the clinical and sociodemographic attributes of student and control groups. It was not surprising to discover that the student group contained a greater proportion of unmarried persons living outside the family home. Other significant findings may be accounted for by likely differences in the social class composition of the groups. Thus, receipt of violence, episode of parasuicide by near relative, overcrowding and criminal record have all been shown to be related to social class in the parasuicide population, with greatest prevalence found among the semi- and unskilled manual groups (Buglass, 1976). The difficulty of drawing any direct conclusion from the P values obtained in repeated significance tests on the same data, also has to be recognised.

On the basis of this evidence, it would appear reasonable to conclude that concern about the extent of suicidal behaviour among students may be misplaced. However, the discovery of a lower suicide rate in this group is unexpected and requires replication; and while the findings in relation to parasuicide confirm those reported from Oxford, they may not be generalisable to other cities or towns which have less well developed student health services. The data presented here should certainly not be used to justify a complacent attitude towards mental health problems in the student population.

Acknowledgements

Thanks are due to Professor I. Oswald, Drs A. Proudfoot and L. Prescott and staff of the Regional Poisoning Treatment Centre for their co-operation and to the psychiatric registrars who recorded data on all parasuicide patients described here. The help of Mrs P. Clough, Mrs J. Foster, Mrs M. Durie and Mr K. Scott in preparing these data is also gratefully acknowledged. Further information was kindly provided by the General Register Office (Scotland), Mr J. Arrundale at the Scottish Education Department, and principals at the institutes of further education in Edinburgh.

Influence of the Day of the Week and the Weather on People Using a Telephone Support System

E. HRIBERSEK, H. VAN DE VOORDE, H. POPPE and J. CASSELMAN

The calls to a telephone counselling service at Louvain, during a 21-month period, from one telephone zone were analysed. Data were studied in relation to the type of weather, which was recorded every day. Calls made by women about health and interpersonal problems showed a relationship to the weather, while calls apparently motivated by masturbation intentions from male callers increased when the weather improved.

From ancient times, man has tended to link, mostly on the basis of subjective feeling, weather, season, and climate with health, mood, and behaviour (Licht, 1964), as indicated by many traditional proverbs and expressions (Pastor, 1934; Dufour, 1978). Weather is also an important factor in social life, illustrated in the importance attached to it in travel brochures and marketing.

However, there has been little scientific investigation into this matter, though a weather dependency or meteorological aetiology has been put forward for almost every disease (Tromp, 1980), and for some, a direct relationship with weather and climate can certainly be found. Few doubt the pathogenetic influence of long-term UV exposure on the skin (Roelandts and Degreef, 1980) or the influence of cold and foggy weather on symptoms of angina pectoris (Bullock & Hall, 1982; Feldman & Conti, 1982), but for many other diseases, research results are contradictory, and conclusive evidence is still missing. In psychiatry, though, a great deal of attention has been given to the possible influence of the weather and season on diseases: many reports are available on the seasonality of the incidence of depression, mania, suicide, and schizophrenia, but due to the numerous intervening and sometimes unknown variables, a convincing connecting theory has still to be drawn up (Hare *et al*, 1974; Symonds & Williams, 1976; Mawson & Smith, 1981; Meares *et al*, 1981; Hare, 1981; Parker & Walter, 1982; Shur, 1982; Rosenthal *et al* 1984; Watson *et al*, 1984).

By investigating the influence of the weather on the number and type of the calls to a telephone counselling service, we tried to investigate the possible influences of the weather on people with physical or psychosocial problems. We therefore analysed the calls to the service in Louvain, in relation to three types of weather.

The concept of telephone counselling service has existed for about 30 years in Europe. Though the original purpose was suicide prevention, it gradually developed into a more general counselling service for people with problems. In this context, a service was first set up in Belgium in 1959; there are now five in the Flemish part of the country, whereas the Walloon part has three. Our service (Tele-Onthaal) functions on the level of basic community health care. Its aim is to give telephone counselling and support, 24 hours a day; this is done by volunteers, supervised by a permanent staff. There are 100 members, on duty in shifts, who receive training, with follow-up, in giving prompt and accurate help to people with problems. For every call, the volunteer on duty completes a form, which gives a profile of the caller, including sex, age, marital status, and the type and reason for the call. A short summary of the conversation is made on the back. On this precoded form, the volunteer can check off one possibility for every item and up to two possibilities for problems dealt with during the conversation.

Method

This report is based on 23 000 calls, made to the telephone counselling service in Louvain during the period from 1 January 1981 to 30 September 1982. The fact that the volunteers on duty change five times a day removed any systematic bias in the completion of the forms. To ensure uniformity of weather conditions, only the 13 191 calls coming from the Louvain telephone zone were retained for study.

Following Poriau (unpublished theses 1972), we used the relative duration of sunshine as a parameter for the weather; he found that the sun, and particularly the number of hours of sunshine, is the most important factor in peoples' subjective appreciation of it. The relative duration of sunshine, i.e. the ratio between the real number of hours of sunshine and the potential hours that day (number of hours between sunrise and sunset) is independent of the season, and has the advantage that only one value for each day has to be taken into account. These observations were made at the Louvain Climatic Institute, and were valid within a radius of about 20 km, corresponding largely to the Louvain telephone zone.

The calls to the telephone counselling service were first studied according to the time of day and day of the week. Holidays were counted as Sundays, because they are subjectively felt to be the same as a Sunday. The unequal presence of the various days of the week in the experimental period forced us to make corrections, to transform the data into comparable material. This was done in two steps. Firstly, an average number of calls was calculated for each day of the week (first part of the formula below). This was then multiplied with the total number of days in the experimental period, and divided by the number of days in a week (second part of the formula). In this way, we calculated a number of calls (N′) for each day, as if each day were equally present in the experimental period.

$$\frac{\text{Number of calls on day X}}{\text{Frequency of day X}} \times \frac{\text{Total number of days (638)}}{\text{Number of days in a week}} = \text{N}'$$

Three types of weather were distinguished on basis of the relative duration of sunshine (RDS); when this was less than or equal to 10%, we designated the weather as 'bad' and called it Weather A. This occurred on 222 of the 638 days. When the RDS was equal to or greater than 60%, we designated the weather as 'beautiful', and called this type C; this occurred on 144 days. When the RDS was greater than 10% but less than 60%, the weather was designated as 'changeable', and was called type B, which was the case on 272 days. In the second part of the study the number and type of the calls were examined according to these types of weather. Corrections had to be made here in the same way and for the same reasons as for investigation of the calls by day of the week.

$$\frac{\text{Number of calls when type X}}{\text{Frequency of type X}} \times \frac{\text{Total number of days (638)}}{\text{Number of types (3)}} = \text{N}'$$

Finally, the calls were investigated according to the seasons and the months of the experimental period. Because the winter of 1981 and autumn of 1982 were not totally covered, they were excluded from the investigation by season. Corrections also had to be made because each season or month does not have the same number of days.

$$\frac{\text{Number of calls in season X}}{\text{Number of days in season X}} \times \frac{\text{Total number of days (549)}}{\text{Total number of seasons (6)}} = \text{N}'$$

$$\frac{\text{Number of calls in month X}}{\text{Number of days in month X}} \times \frac{\text{Total number of days (638)}}{\text{Total number of months (21)}} = \text{N}'$$

To determine the influence of the weather on the calls, a χ^2 test for goodness of fit was used: the expected frequencies were considered to be equal within one sex. Our Null Hypothesis (H_0) was that all spreading of the calls within one sex was based on coincidence. The limit to reject this hypothesis was set at $P<0.01$.

Results

In the first part of the study, it became clear that many more women than men call the service (1.6:1). In both sexes, an obvious increase in the number of calls is seen as the day goes on, with peak periods between 10 and 12 am, 2 and 4 pm, and late at night; there is a slack period in the early morning. All this is more striking in women's calls, but is statistically significant in both sexes (χ^2 male = 943.27; $P<0.001$ and χ^2 female = 1,735.04; $P<0.001$).

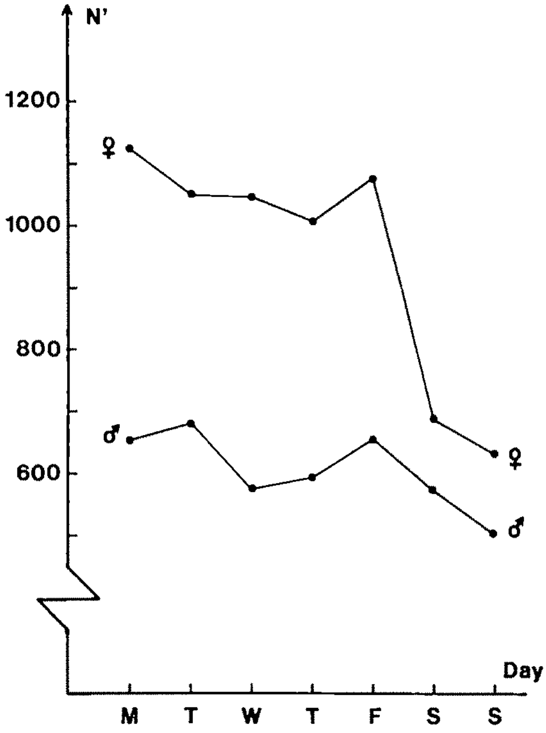

Fig. 1 Corrected number of calls (N′) to Tele-Onthaal according to the day of the week for male and female callers.

At weekends, there is a sudden decrease in the number of calls for both sexes (χ^2 male = 38.64; $P<0.001$ and χ^2 female = 183.43; $P<0.001$), which again is more striking in women's calls. On Monday, the number of calls increase again. The downward trend of the number of calls during the week, which could point to the need for airing problems accumulated during the weekend, was tested with the Spearman correlation test for trends within groups. This did not reach our criteria for significance (Spearman correlation for male −0.68; NS and for female −0.79; $P<0.05$).

The variation of the calls according to the three types of weather was statistically significant for women, with a strong decrease as the weather improved ($\chi^2 = 35.64$; $P<0.001$). Age-specific investigation here revealed no signs of weather dependency, but testing for marital status showed weather dependency. Divorced women and widows seem to call the

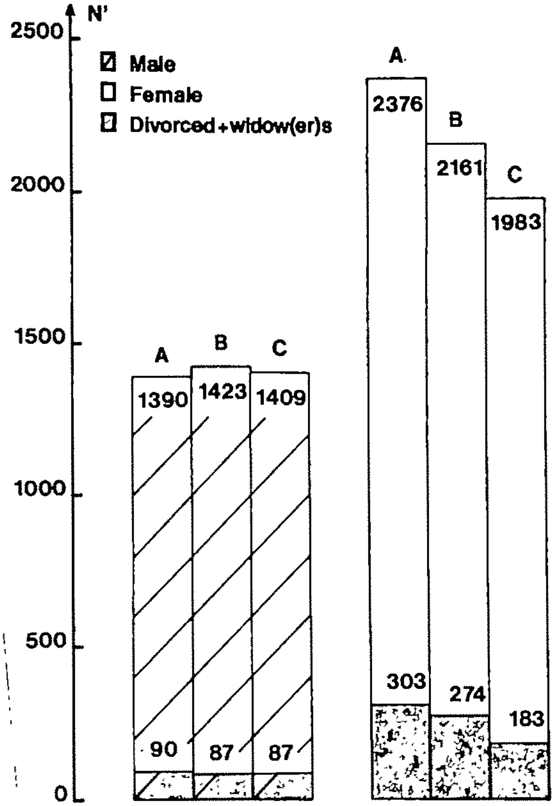

FIG. 2 Corrected number of calls (N') to Tele-Onthaal according to the type of weather for male and female callers. Subgroup widow(er)s and divorced. A = RDS ≤ 10%, B = RDS > 10% but < 60%, C = RDS ≥ 60%.

telephone service most when the weather is bad. This decreases when the weather is beautiful ($\chi^2 = 30.95$; $P < 0.001$). For divorced men and widowers, there was a similar tendency, although by no means statistically significant ($\chi^2 = 0.07$; NS).

Some callers are well known to the service; the frequency and pattern of their calls is entirely different from that of the other groups. This is mainly caused by the great increases in the number of calls concerning sexual problems when the weather improves and, in particular, calls from men whose intention is to masturbate while speaking to the telephone counsellor.

Calls concerning health problems increase significantly for women when the weather is bad ($\chi^2 = 27.15$; $P < 0.001$). In our investigation, this was not seen in men ($\chi^2 = 0.88$; NS). There is also an increase in calls from women complaining of relational problems with their partner when the weather gets worse ($\chi^2 = 22.27$; $P < 0.001$). For men, a similar tendency was found, although not statistically significant ($\chi^2 = 4.13$; NS).

In a third part of the study, we checked these results by investigating the calls by season and month, and this confirmed the results to a great extent. Calls concerning health and relational problems followed a seasonal pattern, with a significant increase in winter ($P < 0.001$). The remarkable increase in calls for masturbation from men during the summer corresponds with the results from the investigation of the calls for sexual problems according to the type of weather.

Discussion

The distribution of calls during the day and the week shows that people seeking help tend to telephone when they are sure to be undisturbed. In Belgium, and certainly in Louvain, women are the greatest part of the unemployed, and a large number of them are housewives; when husband and children are out, they thus have an opportunity to call undisturbed, and share their problems with the anonymous telephone counsellor. Many women lack possibilities for social contact and thus for airing their problems, partly due to the differing expectations, social obligations, and life styles of men and women. All this explains, at least in part, the fact that there is a greater number of calls from women, and that the increase in calls during peak periods is greater for women than for men.

Trenkle (1982) and Symonds & Williams (1976), among others, have suggested that women are more sensitive than men to weather, due to hormonal differences. However, even if this is true, other factors surely must be taken into account: many women remain indoors and postpone shopping, visits, and walks when the weather is bad. This can create loneliness, making a call to a telephone counselling service more probable. Women, furthermore, are often more sensitive to fashion than men, and their clothes are frequently less adapted to bad weather. Sun and warmth have become selling 'products' in many women's magazines, travel brochures, and fashion books. Therefore, women are more sensitive to weather parameters, in part due to the predominance in the media of an image of beautiful weather that influences them to live a certain style of life.

Loneliness is most felt when possibilities for contact are scarce, for instance because of bad weather. It is not surprising that it is at these times that divorced people and widow(er)s tend to call most to Tele-Onthaal.

The calls for sexual problems, most of them from well known male callers concerning masturbation, show a completely different pattern from that of other calls. The peak periods are seen when the weather is beautiful. Michael (1983) found the same tendency when he studied the variation in time of different forms of sexual violence in the United States.

It is not surprising that calls for health problems increase when the weather is bad. It is well known that the subjective complaints as well as the objective symptoms of many diseases increase in winter, or when the weather is bad.

Problems of relationships between partners seem to have the same tendency, again more striking in women's calls. People working out of home, who can bury themselves in their work or share their problems with colleagues, are likely to deal more easily with such problems.

The effect of bad weather can also partly be explained by territorial feelings. These become more prominent when one is obliged to stay indoors, sharing space with several people, so making the space smaller for each individual, and thus also restricting the possibilities for privacy.

The results of this study show that there is indeed an influence of the weather on calls to this telephone counselling service, particularly on calls from women concerning health and relationship problems. Though lack of opportunities for social contact or entertainment, and a greater concern with fashion may be relevant, this could indicate a greater sensitivity to the weather in women. In men, more of a weather influence was found in the calls relating to masturbation. It was found that women telephone Tele-Onthaal more than men, and that both sexes place importance on an undisturbed conversation with the anonymous telephone counsellor.

Measuring the Rising Tide

How Many Dementia Cases will there be by 2001?

B. INEICHEN

Numerous surveys have attempted to estimate the prevalence of dementia. Despite difficulties of measurement, evidence suggests figures may be lower than is generally realised. Factors which are likely to affect prevalence rates are discussed. Forthcoming changes in the demography of old age indicate that increases in the prevalence of dementia may have been seriously underestimated.

The rapid increase in the number of elderly people, especially the very elderly, is widely recognised, and is likely to continue into the next century. By then there will be almost nine million people of 65 years of age or more in Britain, nearly half of whom will be over 75. Over a million will be at least 85 years old (OPCS, 1985).

This means almost inevitably a growth in the numbers of mentally ill old people, the so-called 'Rising Tide' (HAS, 1982). Information on the extent of mental illness, especially dementia, among the elderly is becoming available on an increasing scale, but as yet much remains scattered and relatively little-known. This paper attempts to bring together this literature, and to apply it to estimate the likely increase in dementia sufferers by the end of the century.

Problems in measuring the prevalence of dementia

Counting the number of dementia sufferers is not easy for the following reasons:

(i) There is no universally agreed criterion for what constitutes 'a case' (Davis, 1984); there are particular difficulties at the 'mild' end of the spectrum (Henderson, 1983; Cooper & Bickel, 1984; Henderson & Huppert, 1984). Impairment of intellectual function, especially memory, is a universally agreed feature of dementia, relatively easy to measure. Deterioration of behaviour is often also present but creates greater difficulty of measurement. Gilleard (1984) has an extended discussion of the clinical syndrome of dementia. Epidemiological surveys have used a range of techniques for case identification, including psychiatric interviews and cognitive tests. Gurland (1980) and Gardner (1984) summarise some of the more popular cognitive tests. Kay *et al* (1985) report on the use of a variety of tests and cognitive procedures. Jorm and Henderson (1985) suggest improvements in the use of one particular diagnostic tool, the DSM-III.

(ii) Demographic changes influence prevalence, in view of the age-related nature of dementia. It is often difficult to estimate precisely the denominator for any particular investigation.

(iii) Few studies have been sufficiently robust in their methodology to provide firm answers. Much dementia remains outside the service net (Williamson *et al* 1964; Parsons, 1965; Helgason, 1977), making any study drawing on service usage for its sample of limited value. Studies dealing only with populations known to particular services (e.g. Adolfsson *et al* 1981; Molsa *et al* 1982) are excluded from the present discussion. Services themselves are subject to enormous local variation. Reliable large-scale surveys are expensive and laborious to conduct, and therefore rare. Most existing studies have used samples numbered in hundreds rather than thousands; the number of identified dementia sufferers is therefore small and subject to experimental error. High refusal rates, as found in some studies, are another source of potential error.

(iv) A wide range of sociocultural factors may influence the number of dementia sufferers. The degree of isolation of elderly people from their relatives, for example, is influenced by changes in family size, family cohesiveness, housing styles etc. (Blazer, 1980) and this may be increasing in Britain (Roth & Mountjoy, 1980). Changes in nutrition, level of education, and other sociocultural factors may also influence the extent of dementia.

(v) In our present state of knowledge only an approximate answer can be given to the question of how long dementia patients survive, although one recent study (Diesfeldt, 1986) reports an average duration of 7.2 years for an institutionalised sample.

Findings in published studies on the prevalence of dementia in old age

Many previous writers on the subject (OHE, 1979; Roth & Mountjoy, 1980; Arie & Jolley, 1982; McCarthy, 1982; Norman, 1982; Pitt, 1982; Davis, 1984; Mahendra, 1984; Miller, 1984; Wilkin *et al*, 1984) have contented themselves with quoting from the work of Kay *et al* (1964, 1970) done in Newcastle in the early 1960s, as the most recent, or the most valued, or indeed the only work on the subject of the prevalence of dementia. However, a score of studies have been published subsequently, many with very different findings. Attempts to bring these studies together have been no more than partial: Kay & Bergmann (1980), for instance, list 17 studies, but only three of these have been published since 1970. (See also Mortimer *et al*, 1981; Gurland & Cross, 1982; Henderson, 1983; Mortimer, 1983; Henderson & Kay, 1984; Eastwood & Corbin, 1985).

The UK studies are as follows:

Kay *et al* (1970). Interviews with representative samples of people over 65 living at home in Newcastle-on-Tyne in 1960 and 1964. ($n = 758$); 47 cases (6.2%) were reckoned to have a firm diagnosis of Chronic Brain Syndrome, in nearly every case due to senile or arteriosclerotic dementia.

Gruer (1975). A 1-in-20 sample from Scottish borders, covering whole population, identified from executive council lists and hospital populations. Stratified for urban/rural, male/female and four age-groups. 762 out of 835 interviewed (success rate of 91.3%). Fieldwork 1971/2, 6.9% rated as definite or assumed dementia, another 1.4% possibles; 41% had psychological symptoms, the majority of which were not recorded by their GP.

Broe *et al* (1976). Sample of 808 elderly people living at home in northern Glasgow and Kilsyth. Three surveys amalgamated: two stratified by age to give equal numbers under and over 75. Refusal rate 20–30%. Dates of fieldwork not given. Criteria for senile dementia closely followed Slater & Roth (1969). Interviewed at home by a doctor; most doubtful cases examined by a neurologist: 1.6% of those aged 65–74, and 7.2% of those over 75, rated as suffering from severe or moderate dementia.

Gilmore (1977). Study of 300 people of 65-plus, living at home. Three (1%) rated as suffering from severe dementia, defined as "incapable of coherent and sustained speech, of indicating their needs or of responding to commands". Another 13 (4.3%) rated moderate: "some recent loss of memory, obvious difficulty in concentration, fluctuating disorientation for time, place and event". Another 12 (4%) rated as mild dementia, with variability in concentration, resembling a state of preoccupation, in combination with some recent memory loss of trivial information with occasional "personal and geographical" orientation lapses.

Bergmann *et al* (1979). Sample of 800 on lists of two GPs in Newcastle. Diagnosis of dementia based on (i) use of psychogeriatric assessment schedule to diagnose probable organic psychiatric disorder and (ii) interview with psychiatrist using Geriatric Mental State schedule (Copeland *et al*, 1976). Another psychiatrist arbitrated in disputed cases: 25 subjects reckoned to be suffering from dementia.

Gurland *et al* (1983). Sample of 489 people aged 65 or more on GP lists and living at home in London were approached: 93 could not be contacted or refused to be interviewed; 396 were interviewed—a response rate of 81%. Assessment by Comprehensive Assessment and Referral Evaluation (CARE), a semi-structured interview developed by the team, and administered by a psychiatrist with a special interest in psychogeriatrics. A 22-item scale of dementia was constructed, composed of errors in memory, orientation and learning; in reporting age, date and significant events; in learning the interviewer's name; and in recalling the names of famous persons. A score of 6 or more on this scale was considered to be particularly likely to be indicative of a severe clinical disorder. Ten subjects (2.5%), all female, eight aged over 80, reached this level. Similar techniques have produced higher rates in New York (in the same report) and in Hobart (Kay *et al* 1985).

Clarke *et al* (1984, 1986). The entire population (1203 people) over the age of 75 living in and around Melton Mowbray, Leicestershire, were approached in 1981: 95% were interviewed. Refusals were not thought to have major health problems. Dementia was defined as a score of 7 or less on the Information Orientation Sub-test of the Cognitive Assessment Scale taken from Pattie and Gilleard (1979); 4.5% came into this category and another 3.5% were unclassifiable.

Maule *et al* (1984). Random sample of 487 people aged 62–90 drawn from GP's lists (i.e. including those who had been in long-stay institutions for less than 2 years) in North Edinburgh interviewed by a psychiatrist in 1968–1969. Psychiatric assessment based on answers to a semi-structured questionnaire and from the behaviour, mood and attitude of the subject at the time. Chronic Brain Syndrome defined as the permanent and irreversible decline of all mental abilities; moderate or severe cases were those in which clinical dementia was present and included senile dementia, arteriosclerotic dementia and other cerebral organic syndromes. Only three cases of severe CBS were recorded (0.6%) but in 14 cases (2.9%) the impairment was classed as clinical dementia and was severe enough to interfere with self-care.

Table I, drawing on the above studies and those based on surveys conducted outside the United Kingdom, shows an overall rate for dementia (of all levels of severity) which ranges from 24.6% to 2.5%. Despite some interesting consistencies (e.g. the clustering of the four Scottish studies) the range of estimates make this information of little use; it is more practical to concentrate only on those surveys which produce a more restricted definition of dementia.

TABLE I
Studies of the overall prevalence of dementia

Author	*Date of publication*	*Country*	*Age range*	*Sample size*	*Overall rate (%)*
Sternberg & Gawrilova	1978	USSR	60+	1020	24.6
Weissman *et al*	1985	USA	65+	2588	16.1

Nilsson	1983	Gothenberg	70	404	Whole community	1.0	—
Maule *et al*	1984	Edinburgh	62–90	487	GP lists	0.6	2.9

Table II includes only those surveys which include a measure of severe dementia, with or without a further measure of moderate dementia; or which include only one measure of dementia. It also incorporates the sampling technique used. Weyerer's study in Bavaria is the only one to exceed the figure of Kay *et al* of 6.2% for severe dementia alone. Eight of the studies produce a figure of less than half of that found by Kay *et al*. The recent study in Hobart (Kay *et al* 1985) also reports low figures for severe dementia among its sample of over-70's, using a variety of different measuring techniques.

Studies of Incidence

Very few studies of incidence have been carried out due to the considerable practical problems of such research.

Mortimer *et al* (1981) quote the Newcastle studies and other work, suggesting the annual incidence figure for senile and arteriosclerotic dementia may be of the order of 1.4% of over-65s. Kay & Bergmann (1980) quote four other studies which show very much lower rates for chronic brain syndrome. This may reflect the technique of enquiry more than anything else: three of the four low-incidence studies are derived from case registers, whereas the Newcastle study is based on interviews.

One Swedish study is particularly notable. Hagnell *et al* (1981) studied the total population of Lundby (2550 people) between 1947 and 1972, finding that over that time 'age psychosis' appeared to be decreasing, for elderly men and for women over the age of 80. This the authors attribute to the improved security and material circumstances of elderly people in Sweden. Bergmann & Jacoby (1983) suggest the causes might include improved physical health, better nutrition and the control of high blood pressure by hypotensive drugs, reducing the incidence of stroke.

Meanwhile, estimates based on studies in the 1960s have suggested that about one in five people will end their lives suffering from dementia (Mortimer *et al*, 1981); almost 30% of 85-year-olds will dement (Sluss *et al*, 1981). Research designed to test comprehensively ideas on the onset and incidence of dementia would clearly involve frequent and prolonged contact with a large sample, and there appears little prospect of such work ever being conducted..

What does the diagnosis of dementia in old age mean?

The range of techniques used to establish the presence of dementia in the quoted prevalence studies is clearly very considerable, and a contributory factor to the great range of answers that they produce.

Gardner (1984) provides a guide to the clinical assessment of dementia. Henderson (1983) gives the Royal College of Physicians' 1980 definition, and points out that the rubric of dementia applies to 100 different diagnoses in which higher brain function is impaired; only two principal categories (Alzheimer type and multi-infarct dementia) are recognised in the elderly. Pitt (1982) considers there may be a third category of dementia sufferers, whose problem is essentially one of forgetfulness. Roth (1985) has an extended discussion of the problems involved in diagnosing and classifying dementia, and Kay *et al* (1985) describe the use of a variety of techniques on one relatively small sample. They note that much of the construction of the testing tools rests upon clinical observation, and feel that their validity is still to be investigated.

Cooper & Bickel (1984) quote four studies where the rate of confirmation of the diagnosis varies from 74% to 90%. Hare (1978), on the basis of a study of 200 admissions to a psychogeriatric unit, found that severe memory loss was not equivalent to dementia: too much emphasis on memory loss led to overdiagnosis. She considered that psychological tests based on parietal signs were good predictors. Other studies quoted by Gurland & Cross (1982) suggest that within psychiatric settings, dementia may be overdiagnosed.

The problem of diagnosis of mild dementia is especially great. It is probable that persons with mild dementia constitute a heterogeneous group: those with low IQ, those with early dementia who subsequently deteriorate, and those whose dementia remains a a mild level (Kay & Bergmann, 1980).

Intervention can make some impact on the level of dementia: mental stimulation has been shown to improve intellectual performance, but for the improvement to be maintained, the stimulation must be consistently applied (Charatan, 1984).

Factors Influencing Prevalence

Sampling technique

Most of the UK studies have used either GP lists or surveys of people living at home to gather their sample. The first technique excludes only those people in long-stay hospitals; the second those in all kinds of institutions. Both approaches produce a wide scatter of results.

Studies using GP lists include Clarke *et al* (1986) who report 4.5% of over 75s; Bergmann *et al* (1979), who give an undifferentiated overall figure of 3.1%, and Maule *et al* (1984), who give 8.6% for overall prevalence, but 0.6% for severe dementia only.

Five surveys (Kay *et al*, 1970; Broe *et al*, 1976; Gilmore, 1977; Gurland *et al*, 1983; Clarke *et al*, 1984) are based on samples of people living at home. Their results range from 1.6% (Clarke *et al*, 1984) to 9.3% (Gilmore, 1977) for overall prevalence, and from 1.0% (Gilmore, 1977) to 6.2% (Kay *et al*, 1970) for severe dementia alone.

Age

There is clear evidence from numerous studies that dementia is age-related (Kay *et al*, 1970; Helgason, 1977; Campbell *et al*, 1983; Henderson, 1983; Maule *et al*, 1984), although Henderson & Huppert (1984) point out that in some earlier studies prevalence falls abruptly in the over-85s. Whether or not mild dementias proceed to more severe conditions is unclear. Mortimer (1983), also on the basis of early studies, considers that the incidence rate may level off at around age 75; evidence from the oldest age-groups is too slender to judge if the trend continues. He quotes autopsy studies which suggest that over the age of 80 there may be a reduced risk of developing the brain lesions characteristic of Alzheimer's Disease.

Sex

There is considerable evidence (Weyerer, 1983; Cooper, 1984; Maule *et al*, 1984) that even controlling for the greater longevity of women, more elderly women become mentally ill than elderly men.

Dementia alone is less clear-cut. Some evidence (Broe *et al* 1976; Helgason 1977; Campbell *et al* 1983; Bergmann 1985) shows little or no difference between the sexes. Other surveys (Gurland *et al* 1983; Clarke *et al* 1984, 1986; Maule *et al* 1984; Weissman *et al* 1985) find more dementia among females. However, Scandinavian investigators (Bollerup, 1975; Persson, 1980) find an excess of males. Perhaps their evidence is influenced by the effects of alcoholism, which so dominates the psychiatric scene in those countries.

Social class

Cooper (1984) notes an inverse association between mental disorder and physical disability with occupational class among elderly people. The excess of mental illness is accounted for solely by organic conditions. The rate of mental illness was especially high among people living in poor material conditions.

Very little evidence is available specifically on dementia. Kay *et al* (1964, 1970) found no association between dementia and social class, but few other writers have considered the subject. Gurland (1981) and Weissman *et al* (1985) found highest rates among those with least education. The difficulty of diagnosing accurately dementia among those of low intelligence or poor education has been noted (Gurland, 1981; Henderson, 1983; Henderson & Huppert, 1984). Murphy (1982) notes more major social difficulties, poor physical health and depression among working-class than middle-class elderly people in her East London sample.

Location

Most surveys have been held in urban locations. None has been held with an exclusively rural sample; three (Gruer, 1975; Weyerer, 1983; Clarke *et al*, 1984, 1986) have taken place in areas comprising a mixture of small town and rural areas, and these have produced very different findings. Gurland *et al* (1983) produce very different rates for New York and London, using identical methodologies in the two cities. Other research (e.g. Srole *et al* 1961) has found a high rate of mental disorders among New Yorkers generally.

How long do dementia patients live?

Dementia appears to be associated with premature death, although the relationship is not clear-cut. Significantly more of the samples of Kay *et al* (1970) and Maule *et al* (1984) had died within 4 or 5 years of the initial diagnosis. The more severe cases in the latter sample were all dead within 7 years, although the milder cases had a better record of survival. Gurland & Cross (1982), in contrast, quote other published studies which show that persons with mild dementia have an increased rate of mortality. A study of elderly twins found survival associated with the preservation of competent performance in completing psychological tests (Jarvik & Falek, 1963). Several studies (Larsson *et al*, 1963; Heston *et al*, 1981; Whitehead, 1981; Henderson & Kay, 1984) show increased mortality is associated with early onset of dementia, but not with onset over 80. In a review of longitudinal studies, Christie (1985) found that survival time among dementia patients appears to be lengthening. Other research yields little in the way of firm conclusions.

Studies of survival, using contact with services as a measure of onset, are of course notoriously unsuitable for estimating survival rates among elderly people with dementia. They may reflect nothing more than a service's efficiency in tracking down and preserving patients, and be misleading over the question of the influence of the condition *per se*. Gruenberg (1978) found that for every person over 65 in a Mental Hospital in New York State, there were 4.5 people of the same age who were at least as mentally disabled but who were not in hospital. The ratio increased with age: some severely mentally disabled old people probably die without ever being hospitalised.

Gilleard (1984) discusses the question of the onset of the condition at some length, pointing out that the criteria laid down by researchers to determine onset are often vague and rely on relatives' recall. Levels of disagreement over 2 years are not uncommon. He considers the average survival time in hospital is about 2 years for dementia patients; he finds no difference in mortality rates between demented elderly people at home and in institutions, concluding:

> . . . the expected survival of elderly individuals developing dementia does not greatly differ from that of elderly individuals not developing dementia, unless the onset of mental decline occurs before the age of 75. It is probable that supporters who care for an elderly relative beginning to show signs of mental deterioration may expect, therefore, six to eight years of coping, with ever-increasing problems. Such extended caregiving may involve a gradually increasing burden for family members that may extend beyond their limits to maintain care over such a prolonged period (1984).

How many dementia cases?

The study by Kay *et al* (1970) suggests a figure of 6.2% of all over-65s for the prevalence of dementia. However, more recent work indicates this figure may be too high. Mortimer *et al* (1981) propose a figure of 4.15%, based on the median figure for eight surveys. However, the most recent research suggests that this figure may itself be too high. Three recent UK studies which apply the most rigorous criteria in identifying 'a case' (Bergmann *et al*, 1979; Gurland *et al*, 1983; Maule *et al*, 1984) have very similar rates if the 'clinical dementia' found by Maule *et al* is added to 'clinical brain syndrome'. The mean rate for dementia for these studies is 2.83% and for their summed samples is 2.91% (see Table II).

Applying these flat rates to increases in national population, drawing on mid-year estimates for 1983 and the population projection for 2001 (OPCS, 1985), gives an increase of 4.8% of cases over that period.

However, the changing age structure of the elderly population means that a flat-rate estimate for dementia based on the number of over-65s is of little use. Age- and sex-stratified figures derived from Kay *et al* (1970) and two other studies in the 1960s have been calculated (Kay & Bergmann, 1980). Applied to national figures, these show a very similar increase (4.7%) to the flat-rate figures.

In view of the lower figures suggested by more recent research, a simple rule-of-thumb is suggested: 1% of 65–74s, 10% of 75 and over. Applying these rates yields lower figures than those of Kay & Bergmann, but a much larger increase (17.2%) between 1983 and 2001. In local areas containing an above-average number of elderly people the increase will be even larger: population projections for Bath Health District, for example, indicate an increase of the order of 33.6%, and an even larger increase may be calculated for health districts already containing a very large proportion of elderly people.

The Present State Examination Change Rating Scale

K. H. TRESS, C. BELLENIS, J. M. BROWNLOW, G. LIVINGSTON and J. P. LEFF

The development and use of a new psychiatric symptom change scale based on the Present State Examination (PSE) – the PSE Change Rating Scale – is described. The advantages of the PSE are retained (the extensive glossary, the diagnostic facility and the standardised interview technique) while improving its sensitivity to change and decreasing its administration time. The scale has been designed to prevent feedback of results and 'halo' effects: it has proved highly reliable in use across raters with different backgrounds and experience. The scale has been used to monitor drug effects on clinical state across a variety of diagnoses and examples of its use are given.

One of the problems affecting research on the biological concomitants of psychotic illness has been to elucidate the causes of change in clinical state. A common approach has been to test patients initially when they are not receiving medication and to repeat the test some time later after treatment has been instituted. Changes in response to the test between the two occasions could then be due either to the natural history of the symptoms or to an effect of the medication itself. In order to decide between these two alternatives it is necessary to be able to measure sensitively changes in clinical state.

Ideally, a psychiatric clinical rating instrument should:

1. (1) generate data which provide the basis for clinical classification;
2. (2) be sensitive to change in symptoms;
3. (3) provide clear and mutually exclusive definitions of the symptoms;
4. (4) utilise a standardised interview;
5. (5) be acceptable to interviewers and subjects alike.

Manchanda & Hirsch (1986) surveyed five psychiatric journals over 3 years to establish which rating scales were in common use for schizophrenia. Of the six scales in most common use only four were applicable for all psychiatric diagnoses and for both acute and chronic disorders. These were: the Brief Psychiatric Rating Scale (BPRS) (Overall & Gorham, 1962), the Comprehensive Psychopathological Rating Scale (CPRS) (Åsberg *et al*, 1978), the In-patient Multidimensional Psychiatric Scale (IMPS) (Lorr & Klett, 1967) and the Present State Examination (PSE) (Wing *et al*, 1974). They found that the BPRS is able to satisfy points 2 and 5 above but does not give data for a clinical classification, provide clear definitions or use a standardised interview. The same criticism is true for the IMPS whereas the CPRS satisfies points 2, 3 and 5. The PSE, while satisfying points 1, 3, 4 and 5, was found to be somewhat insensitive to change with, for most symptoms, a 3-point scale and, for some, a 2-point scale compared, for instance, to the 7-point scale for the BPRS. Three points seem to provide too narrow a scale for the sensitivity to change required. This reflects the fact that the PSE was constructed as an instrument for assessing the patients' current psychopathology, and was not primarily designed as a change measure. However, its suitability for measuring change is an empirical question to be studied.

This was the starting point for our attempt to modify the PSE in order to increase its sensitivity to change. A further consideration was the length of the interview. In a floridly ill, psychotic patient, the PSE generally takes 45–60 min to administer. To repeat this procedure at regular intervals on a large number of patients would clearly exhaust the interviewer, might well alienate many of the patients, and would be difficult to fit in with the demands of a clinical job. Therefore, we were also concerned to decrease the administration time of repeated interviews.

Method

The PSE Change Rating is administered in the following manner. Initially, a PSE (9th edition) is administered to the patient by a trained interviewer according to the method described in Wing *et al* (1974). The symptoms that are not rated positively on this interview are discarded, (along with symptoms rated 8 or 9) and the subsequent ratings are made only on items that are rated positively. *The interviewer retains the PSE form throughout the rating period and uses it as the baseline for the ratings.* The words the patient employed to describe the symptoms initially are used as probes in subsequent interviews.

The subsequent ratings are made using a booklet made up of slips of paper. Each slip has only one of the symptoms

Symptom ratings compared to admission

0	Completely remitted
1	Markedly improved
2	Moderately improved
3	Minimally improved
4	Unchanged
5	Minimally worsened
6	Moderately worsened
7	Markedly worsened

FIG. 1. Symptom change scale used for the PSE change rating.

rated positively for that patient typed on it and the slips of paper are in random order. The exception is behavioural observations (PSE items 108–139) which are presented at the end of the booklet when the rater will have observed the patient for the length of the interview. The rater is asked to rate each symptom separately using the obligatory questions and probes from the PSE schedule on a scale 7—markedly worsened to 0—completely remitted (see Fig. 1 for complete scale) *compared to the state of the patient at the initial PSE.*

The rater works through the booklet in the order given without returning to any symptoms. This eliminates the possibility of 'halo' effects (Hilgard *et al*, 1971)—the tendency to rate all related symptoms as better or worse together. When the booklet is completed it is returned to the secretariat so that 'carry-over' effects from one occasion of rating to the next are minimised i.e. the raters do not see their ratings again. Any new symptoms that appear (raters are asked to use general probes) are written on blank slips provided at the end of the booklet and are then included in the next rating booklet. When a symptom has been absent (score of 0—completely remitted) for 3 weeks it is omitted from the booklet.

Certain of the symptoms are not suitable for the increased frequency of assessment associated with a change score and these have been dropped or modified. They comprise symptoms 26 (primacy of anxiety or depression), 27 (diurnal variation of mood), 39 (pre-menstrual exacerbation), 93–97 (general ratings of delusions and hallucinations), 97–107 (organic psychiatric symptoms). Questions that specify a time period for the occurrence of the symptoms need to be changed to the time period since the last rating. The question for symptom 34 (loss of weight due to anorexia) has been modified to take appetite only into account.

In general the ratings, compared to the initial interview, take into account the frequency, severity and, in the case of psychotic symptoms, conviction (insight) and delusional elaboration. Although a symptom needs to reach a certain level of intensity or conviction to be rated as present on the initial PSE it would need to be totally absent to rate 0—completely remitted—on the change rating. This would often mean that a change rating of 1—markedly improved—would not be severe enough to be rated as present if a full PSE were done. Similarly a psychotic symptom, such as delusion, may no longer be present but, if the patient still believes it *was* happening, the symptom is not completely remitted and should be rated as 2—moderately improved, or 1—markedly improved, depending on the strength of conviction.

Examples of repeated ratings carried out on acute admission psychiatric patients

Five examples of ratings carried out on patients admitted to the research ward are given below. They represent a spectrum of diagnosis from acute-onset schizophrenia to prolonged neurotic depression. All patients had been unmedicated for at least 4 weeks prior to admission. In presenting the change ratings graphically each PSE item can be charted separately. In practice, we have found it most useful to present all psychotic symptoms combined, all neurotic symptoms combined, and then an amalgam of all symptoms (which can be seen in Fig. 2). This gives an overall picture of change.

Case A

This 23-year-old woman had suffered three previous psychotic episodes, each of which began abruptly and resolved within a week or so. She had been prescribed lithium, but was not taking it regularly. The present episode began a week before admission while the patient was holidaying abroad. She experienced auditory hallucinations and delusions of control, and exhibited histrionic and uninhibited behaviour. She was treated with haloperidol up to 6 mg twice daily. Her psychotic symptoms resolved within 2 weeks (see Fig. 2A).

Case B

This 35-year-old woman was admitted after a long period of gradual social decline. On examination she showed self-neglect, irrelevant speech and inappropriate laughter. She complained that people interfered with her thinking and put thoughts into her head. She also heard voices calling her. It was considered that she had been suffering from untreated schizophrenia for several years and she was prescribed oral haloperidol up to a dose of 24 mg twice daily. She showed some improvement and was then changed to injections of haloperidol decanoate, 300 mg every 4 weeks. Her clinical condition stabilised, but she developed uncontrollable akathisia. For this reason her medication was altered to fluphenazine decanoate, 100 mg weekly. Unexpectedly, her symptoms showed a further substantial improvement, which first became evident from the PSE Change Ratings (see Fig. 2B). She was eventually discharged to live with a foster family.

Case C

This 52-year-old man had experienced 17 previous admissions for manic-depressive psychosis. On this occasion he had been sleeping rough for several days and then spent 3 days with the Simon Community prior to admission. On examination he was elated, jocular, irreverent and overactive. He showed flight of ideas, pressure of speech and expressed grandiose delusions about writing a best-seller. He was treated with haloperidol up to a dose of 15 mg twice daily. Lithium was added after the second week, following which all his symptoms rapidly resolved (Fig. 2C).

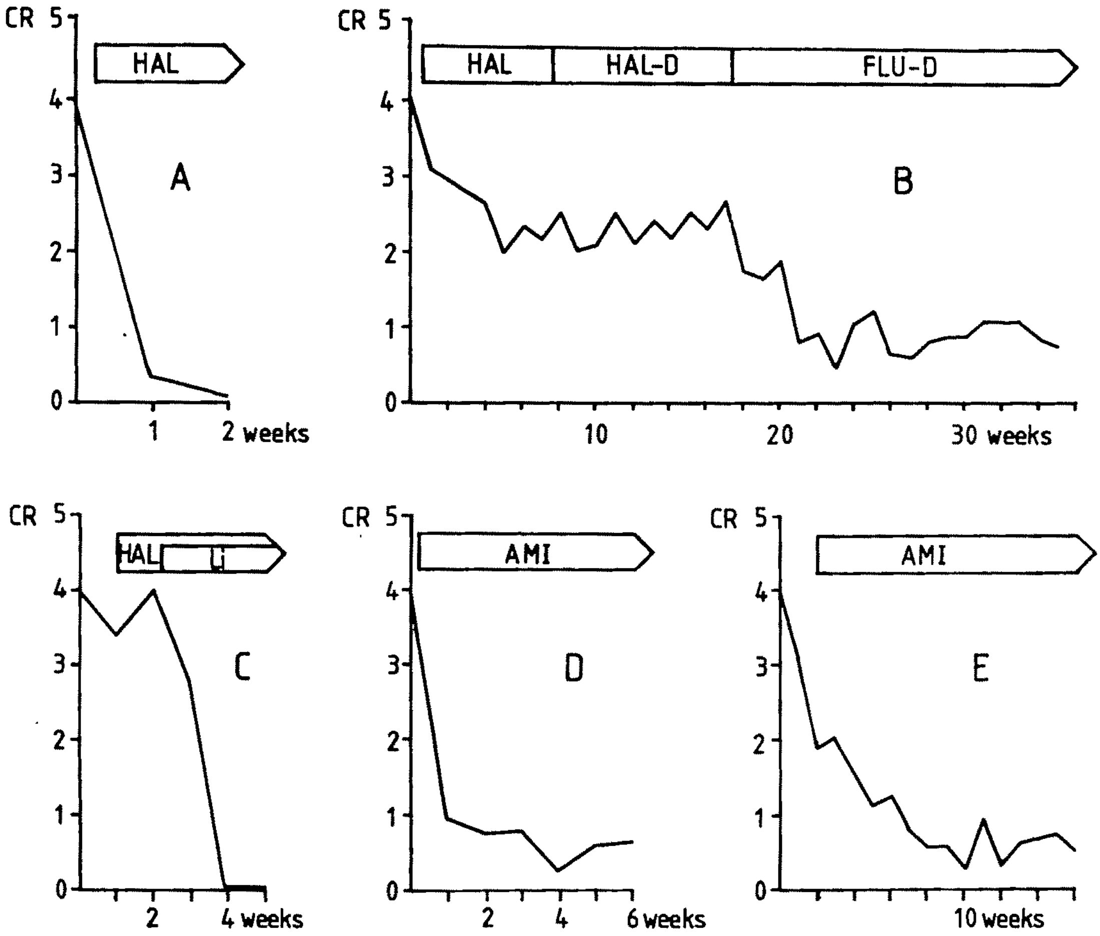

FIG. 2 Illustrations of the symptom change scores over time of cases A–E described in the text. The abscissa is the time in weeks from admission (week 0) and the ordinate is the mean clinical rating for all symptoms (CR). Medication is represented by the names above the graphs. HAL = Haloperidol (oral); HAL-D = Haloperidol Deconate (depot injection); FLU-D = Fluphenazine Deconate (depot injection); LI = Lithium carbonate (oral); AMI = Amitriptyline hydrochloride (oral).

Case D

This 44-year-old man was admitted following an attempt to hang himself. He was divorced and had not worked for 4 years. He had been living in a hostel for 3 months prior to admission. On examination he was depressed and tearful and expressed feelings of severe guilt. He heard people in the street talking about him. He also heard the sound of knives being sharpened at the hostel and believed that he was going to be killed. He was treated with amitriptyline, 150 mg nocte and the psychotic features resolved rapidly (see Fig. 2D), although he was left with persistent feelings of inadequacy.

Case E

This 56-year-old man was admitted with a prolonged bereavement reaction to his mother's death a year previously. He had lived with his parents all his life and never married. Following his mother's death he had moved into a flat of his own, but was completely isolated. He had been drinking excessively and gave a long history of compulsive gambling. He was treated with amitriptyline, 150 mg nocte and showed considerable improvement in his depressive symptoms (see Fig. 2E). However, he remained a very dependent person and continued gambling.

Experiment 1: Inter-rater reliability of the PSE Change Rating Scale

As with any instrument it is necessary to test the reliability of the rating procedure by comparing ratings made on the same patient by different, independent raters. In administering the PSE Change Rating Scale, as with the PSE itself,

TABLE I
Psychiatric diagnosis, sex and age of the patients rated in Experiment 1

Patient no	*Sex*	*Age*	*CATEGO diagnosis*	*Clinical diagnosis*
1	M	21	S+	Schizophrenia
2	F	34	S+	Schizophrenia
3	M	42	S+	Schizophrenia
4	F	39	S+	Schizophrenia
5	M	35	P+	Schizophrenia
6	F	41	P+	Schizophrenia
7	F	33	P+	Schizophrenia
8	F	25	P+	Manic psychosis
9	F	62	M+	Manic psychosis
10	M	29	D+	Depressive psychosis
11	M	44	D+	Depressive psychosis
12	M	37	D+	Depressive psychosis
13	M	41	N+	Depressive neurosis
14	M	26	N+	Depressive neurosis

there are two independent skills involved. One is the actual interview technique and the other is the rating of the patient's replies and behaviour. As the interview technique was identical to that used with the PSE and all raters had been trained to the same standard for administering the interview, it was not thought necessary to check the reliability of this aspect of the procedure. It was decided, therefore, to have one rater interview the patient in the presence of three other raters and for all four to rate the patient independently and simultaneously. This allowed the inter-rater reliability to be calculated for the symptom change ratings.

Subjects

All subjects were psychiatric patients recently admitted to research beds on an acute admissions ward. None of the patients had received medication for at least 2 weeks prior to admission. Patients with a history of drug or alcohol dependence were excluded, as were those over 65 years of age and those suffering from dementia. Apart from these exclusions, the patients were 14 consecutive admissions, who gave consent to the procedures. Information about the patient sample is shown in Table I.

All patients were started on drug regimes after the initial diagnostic PSE and before the first measure of clinical change was made. All the psychotic patients except 2 and 11 were given haloperidol in standard doses, rising weekly until the patient was judged to be well. Patients 8 and 12 also received lithium, patients 10 and 12 received amitriptyline, patient 8 received chlorpromazine and patient 12 had a course of ECT. Patient 2 received only fluphenazine deconate and patients 11, 13 and 14 received only amitriptyline.

Raters

The raters were from varied backgrounds and with differing amounts of clinical experience. Three of the raters remained constant throughout the study but part way through the study one rater (the psychiatric registrar) was changed so that half the patients were rated by one registrar and the other half by the other registrar. Two of the raters were psychiatrists — one a consultant psychiatrist (A) working in psychiatric research and 17 years experience in using the PSE, the other a psychiatric registrar (B) with a few months experience with the PSE. The other two raters were both clinical psychologists — one a senior research psychologist (C) with 4 years' experience of the PSE and the other a basic grade psychologist (D) with 6 months' experience of the PSE. Neither of the two clinical psychologists was involved in the treatment of the patients and they only saw the patients at initial test and to rate them at weekly intervals. The two psychiatrists were involved in the daily care of the patients.

Procedure

Each patient was assessed using the 9th edition of the PSE within 48 hours of admission and before drug treatment was initiated. The initial PSE was carried out by one of the raters in the presence of the remaining three raters who rated the interview independently. At the end of the interview the raters came to a consensus on the symptoms that were present and these were the symptoms used for the ratings the following week. Ratings took place at weekly intervals following the initial PSE. Again, one rater interviewed and rated the patient, while three of the raters rated the patient. All four 'symptom booklets' contained the symptoms in the same random order, with the behavioural observations (PSE items 108–140) at the end. Occasionally, a rater was unable to attend a session and then the session was audio taped for her/him to rate as soon as possible after the interview. This resulted, occasionally, in lost data when behavioural items (other than those rated from speech) were rated. Each patient was rated for 4 weeks or until discharge or other factors made weekly testing impossible. All booklets were handed to a research assistant at the end of the interview. No rater saw the ratings from another rater until the end of the experiment, nor did they discuss their own ratings with each other.

Results

Four of the 14 patients were rated for only 2 weeks and two for 3 weeks. The remaining 8 patients were rated for 4 weeks. Two of the patients had no psychotic symptoms, one patient had no neurotic symptoms and one patient had no behavioural symptoms. The inter-rater reliabilities of the ratings were measured using the Intra-class Correlation Coefficient (unbiased estimator method) (Winer, 1971) and significance tested by the *F* statistic (Bartko & Carpenter, 1976). The results are shown in Table II.

The coefficients range from 0.75 to 0.99, with all but one of the 28 coefficients exceeding 0.8. All the *F* values in the table are significant beyond the 1% level.

This shows an extremely high degree of reliability between raters for these measures. The lowest reliabilities (although still statistically significant) are for the behavioural items. This result is consistent with the findings from studies of the PSE itself (summarised in Wing *et al*, 1974) which also

TABLE II

Intra-class correlation coefficients of total symptom ratings and grouped symptom ratings for the four raters (r_4') in Experiment 1

	Week 1			*Week 2*			*Week 3*			*Week 4*

2. Includes possible ratings of PSE symptoms 4–25, 27–38, 40–54
3. Includes possible ratings of PSE symptoms 108–139
4. PSE symptoms rated in this group of patients 59, 71–81, 86–88, 91, 92
5. PSE symptoms rated in this group of patients 60–63, 68, 70.

found that the reliabilities for behavioural items were lower than for symptoms. Individual symptoms (where these symptoms were sufficiently common to occur in at least four patients) were also subjected to analysis by the Intra-Class Correlation Coefficient and the results are shown in Table III.

Again, the coefficients are high and range from 1.00 (complete accord) down to 0.70. All the *F* values are significant beyond the 1% probability level.

Pearson Product Moment Correlation Coefficients (Ferguson, 1976) were also calculated on the data to compare pairs of raters across the 4 weeks and with all the symptom subgroupings shown in Table III. The smallest range of *r* values was from 0.27 to 0.98 for delusions. However, the majority (76%) of the correlations were above 0.80. Individual raters also followed this pattern—of the *r* values associated with each rater approximately 75% were above 0.80 (A = 74%; B = 79%; C = 80% and D = 73%). It is evident, that high levels of reliability were achieved, even by raters who had relatively little clinical experience.

Experiment 2: A comparison of the PSE Change Rating Scale with the standard PSE scoring method

The results of the previous two sections show clearly that the PSE Change Rating Scale measures clinical change in psychiatric patients and that it has high inter-rater reliability across symptom groupings. However, the introduction of

18	F	25	M+	Manic psychosis
19	F	32	D+	Depressive psychosis
20	F	21	N+	Neurotic depression
21	F	28	N+	Neurotic depression

the 0–7 scale might be an unnecessary complication (Kazdin, 1977) and the relative nature of the remission/relapse ratings might make cross-comparisons of clinical severity difficult. The existing scoring scheme for the PSE (0, 1, 2) is one way of overcoming these possible problems. Thus, it was planned to introduce the existing PSE scoring scheme in parallel with the PSE Rating Scale. In this experiment each patient, on each occasion, was rated by the same rater on the two different rating schemes.

Subjects

The criteria for selection of patients were the same as for experiment 1 and 13 of the patients in Experiment 1 were included in this experiment (patient 9 was not rated). A further seven patients were included making a group of 20 patients. Information about these seven patients is shown in Table IV. Patients 16, 17 and 18 received haloperidol, patient 19 received amitriptyline, patient 15 received diazepam, patient 20 received thioridazine, and patient 21 received dothiepin hydrochloride, and chlorpromazine.

Procedure

The patients were rated by the psychiatric registrars using the symptom booklets in the manner described above but also assigning a score on the existing PSE scale. Each patient was rated weekly—eight by one registrar and 12 by the other registrar. As in Experiment 1 each booklet was given in by the rater as soon as it had been completed.

Results

It became apparent during the course of this experiment that the raters experienced a great deal of difficulty in using the existing PSE scale to reflect the change that they observed. This was seen in the large percentage of symptoms that were not rated on this scale. Of the 90 rating sessions in only 40% were all symptoms on the existing PSE scale rated. In 15.5% of sessions more than 75% but fewer than 100% of symptoms were scored. In a further 15.5% of sessions between 50% and 75% of symptoms were rated and in 29% fewer than 50% of symptoms were rated.

The major problems occurred with those symptoms of the PSE in which the difference between a score of 1 and a score of 2 is a qualitative rather than a quantitative one. That is when an improvement in the patient would not necessarily be associated with a change score from 2 to 1.

In particular for the Schneiderian first-rank symptoms 56–58 and auditory hallucinations 60–64 and visual hallucinations 66 and 67 ratings of 1 and 2 indicate quite different symptoms. For example symptom 57 rates 1 for thought echo and 2 for thought commentary. Symptom 61 rates 1 for hearing single words, 2 for hearing voices based on depressed mood and 3 for voices based on elated mood.

The raters, although well aware of the criteria for rating symptoms on the PSE, found it extremely frustrating being unable to reflect the changes they saw in the symptoms (which is what they had been asked to do) so, instead of marking a symptom absent (by PSE criteria) when it was still present (by PSECRS criteria) they did not rate the symptom by PSE criteria. They also commented on the fact that, when a symptom was originally rated 2 on the PSE criteria there was no way of registering a worsening of the symptom.

Discussion

The difficulty of the raters in using the standard PSE to assess clinical change over short periods of time reflects the fact that its primary purpose was to standardise the cross-sectional examination of the mental state. The clinical examples given demonstrate that its modification has rendered it sensitive to change. The PSE Change Rating Scale was constructed *using psychometric principles* to reduce any possibility of 'halo effects' to a minimum and to avoid the possibility of 'carry-over' effects from one occasion of testing to the next. We have found the inter-rater reliability to be extremely high overall, regardless of the length of clinical experience of the rater. The lowest reliabilities were found for the behavioural items, as with the standard PSE.

A disadvantage of this scale is that, by restricting questioning to symptoms that were present at the original interview, new symptoms might be missed. In practice, with a newly admitted acute psychiatric population, new symptoms seem to be rare. However, this certainly would be a problem with a more chronic population. Supplementary questions could be devised for these populations based on symptoms known to have been present in the past (from notes) or on observation from ward staff. Indeed, this latter source is also available for acute populations and was made use of for probes in this study.

We have found it useful to analyse the data generated by this new instrument as psychotic symptoms, neurotic symptoms, and total symptoms. However, the scores may be displayed for any group of symptoms of interest, or even for individual items.

The assessment of symptom change over short periods of time is essential for the evaluation of any psychiatric treatment, whether pharmacological or social in nature. We have shown the modified PSE to be sensitive to change, easy to use by trained raters, and reliable across diagnostic groups.

Acknowledgements

We gratefully acknowledge the help of Ms P. Arter and Ms L. Owen, research assistants, who were supported by a grant from Janssen Pharmaceutical. Our thanks are also due to Mrs L. Sharon who undertook all the administrative work involved.

CSF Neuropeptides in Euthymic Bipolar Patients and Controls

W. H. BERRETTINI, J. I. NURNBERGER, Jr, R. L. ZERBE, P. W. GOLD, G. P. CHROUSOS and T. TOMAI

Levels of vasopressin, somatostatin, neurotensin, vasoactive intestinal peptide, corticotrophin-releasing factor and adrenocorticotrophin in CSF were determined in lithium-treated and unmedicated euthymic bipolar patients and controls, in a search for a trait marker in affective disorder. No group differences in levels of these peptides were found. Highly significant positive correlations were found among these peptides (with the exception of neurotensin), suggesting that their presence in CSF is functionally significant, as opposed to the result of random diffusion from the interstitial space of the brain.

Bipolar affective (manic-depressive) illness is a cyclic mood disorder of unknown aetiology, in which genetic factors play an important role in pathogenesis (for review, see Berrettini *et al*, 1984). Manic-depressives characteristically have cyclic episodes of markedly sad or euphoric mood, associated with other symptoms, but are well between episodes of mood disturbance. Theoretically, the underlying genetic factors, which increase one's vulnerability to develop affective illness, should be detectable independently of mood state. The study of well-state (euthymic) patients avoids the difficulty of separating state-related abnormalities (associated with acutely ill manic or depressed patients) from trait abnormalities (which may be genetic vulnerability markers). A strategy of studying euthymic patients has been delineated previously (Rieder & Gershon, 1978).

Dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis has been observed in actively ill manic-depressive patients (Sachar *et al*, 1973; Greden *et al*, 1983). Both the abnormal dexamethasone suppression test results (Greden *et al*, 1983) and the hypercortisolaemia (Sachar *et al*, 1973), seen among actively ill manic-depressive patients, are thought to disappear after remission of the depression or mania (Greden *et al*, 1983). Abnormalities of pituitary adrenocorticotrophin (ACTH) response to corticotrophin-releasing factor (CRF) may accompany the dysregulation of cortisol in these patients (Gold *et al*, 1984). These observations led to the conclusion that there is some state-dependent dysfunction of the HPA axis in some patients with affective illness.

The HPA axis is regulated in part by hypothalamic neurons which release CRF, ACTH, vasopressin (AVP), somatostatin (SRIF), vasoactive intestinal peptide (VIP) or other neuropeptide transmitters and/or hormones (Axelrod & Reisine, 1984). For these five peptides, much evidence suggests that brain is the source of the CSF levels, which are regulated independently of the plasma levels (Wood, 1982; Post *et al*, 1982). In the light of the evidence that the HPA axis is regulated abnormally in the actively ill manic-depressive patient, we reasoned that evidence of a state-independent (genetic) abnormality might be found by examination of some HPA-axis-related peptides in CSF. While plasma evidence of HPA axis dysregulation may not be evident in the euthymic patients, CSF levels of HPA-axis-related peptides may be abnormal, representing a biological genetic vulnerability marker. Abnormalities in CSF levels of HPA-axis-related peptides have been reported among acutely ill patients. Significantly lower CSF levels of CRF (Nemeroff *et al*, 1984), VIP (Gjerris *et al*, 1984), AVP (Gold *et al*, in press; Gjerris *et al*, 1985) and SRIF (Gerner & Yamada, 1982; Rubinow *et al*, 1983) were found among actively depressed subjects, suggesting that CSF levels of these peptides should be evaluated as possible trait markers for vulnerability to affective illness.

Recently, it has been reported that VIP is contained and secreted with acetylcholine from some cholinergic neurons (Lundberg *et al*, 1980). VIP may be released into CSF after cholinergic stimuli (Kaji *et al*, 1983). Neurotensin (NT) has been reported to stimulate cholinergic function in guinea-pig enteric neurons (Yau *et al*, 1983); this stimulation is thought to be secondary to increased presynaptic release of acetylcholine and is blocked by SRIF. These observations (that NT and VIP may be modulators of cholinergic function) prompted us to measure CSF levels of these neuropeptides in euthymic bipolar patients to determine whether the reported cholinergic supersensitivity in affective disorder (Sitaram *et al*, 1980; Nadi *et al*, 1984) is associated with abnormalities in the CSF levels of peptidergic modulators of cholinergic function.

Method

Subjects

All individuals participating in this study were out-patients at the National Institute of Mental Health, Bethesda, Maryland. All provided informed consent. The bipolar patients and normal subjects (as well as the clinical details of the lumbar puncture) have been previously described (Berrettini *et al*, 1985*b*). Briefly, euthymic bipolar patients (who were treated solely with lithium for at least 1 month prior to study) and normal volunteers underwent a lumbar puncture as an out-patient procedure after 2 h of bedrest. In addition, 15 of the lithium-treated patients discontinued lithium for at least 2 weeks to provide a second CSF sample in the unmedicated state. Thus, for these patients, paired CSF samples, on and off lithium, were obtained.

Peptide radioimmunoassay

CSF concentrations of immunoreactive human CRF were measured as previously described (Roy *et al*, in press), except that unextracted CSF was used.

VIP radioimmunoassay kits were obtained from Immunoclear Corporation (Stillwater, Minnesota). VIP was determined in duplicate 0.450-ml aliquots of CSF. Recovery of added standard was 90%. Final volume was 0.650 ml. The limit of detection was 4 pg/tube.

A volume of 0.200 ml of unextracted CSF was used to make each AVP determination, as previously described (Zerbe *et al*, 1982).

SRIF was determined on 1.00 ml of lyophilised CSF, as described previously (Patel & Reichlin, 1979; Rubinow *et al*, 1983), and levels were corrected by indexing to chloride concentration.

NT radioimmunoassay kits were purchased from Immunoclear Corporation (Stillwater, Minnesota). NT was determined in duplicate 0.400-ml samples of CSF collected from a 1-ml fraction to which 0.020 ml of concentrated perchloric acid was added. Samples were adjusted to neutral pH with 10-M NaOH before assay. Recovery of added standard was 90%, and the limit of detection was 35 pg/ml.

For the ACTH radioimmunoassay, Sep-Pak cartridges were washed with 10 ml of methanol followed by 10 ml of distilled water. Aliquots of 0.6 ml of CSF were applied to the cartridges which were then washed with 10 ml of distilled water. Immunoreactive ACTH was eluted with a mixture of TEAF buffer (1% formic acid, pH 3.2 with addition of triethylamine) and acetonitrile (4 : 6, v/v). The eluent was lyophilised and the residue taken up in assay buffer (0.63-M Na_2HPO_4 and 0.13-M Na_2EDTA, pH 7.4), containing 0.02% Na_2NO_2, 0.1% triton X-100 and 250 KIU of aprotinin/ml. The recovery of ACTH by this procedure is 85–95%. The antibody was obtained from IgG Corporation (Nashville, Tennessee, ACTH-1). Both standard and trace were $ACTH_{1-39}$. ACTH labelled with ^{125}I was prepared using the chloramine-T method (Greenwood *et al*, 1963). The specific activity was approximately 450 Ci/g. The methods of the radioimmunassay have been previously described (Orth, 1979). The detection limit is 3–5 pg/ml.

Analysis of data

A general linear models procedure was used to assess the effects of age, height, weight and sex on CSF peptide levels. ACTH levels in CSF were corrected for a sex effect. Males ($n=33$, $\bar{x}=22.2\pm5.7$ pg/ml) had significantly higher ($P<0.005$) values than did females ($n=34$, $\bar{x}=18.4\pm4.7$ pg/ml). No other peptide was altered significantly by age, sex, height or weight.

Group *t*-tests were performed to compare euthymic bipolar patients and controls. Paired *t*-tests were used to study the effect of lithium, using those patients from whom paired CSF samples were obtained. Pearson correlation coefficients were calculated for the three separate groups of data (and on all individuals combined) to examine the relationships between these CSF neuropeptides. Z transformation of the correlation coefficients was done to evaluate possible significant differences in correlation coefficients between groups.

All ACTH, CRF, VIP and NT levels were measured in one assay. The coefficient of variation within an assay was less than 15% for all assays. SRIF and AVP levels were measured in two separate assays.

Results

The levels of the six neuropeptides are shown in Table I. No group differences (*t*-tests) or effects of lithium (paired *t*-test) were found, except a trend ($P=0.05$) for CSF VIP to be lower during lithium treatment.

As shown in Table II, a number of significant positive correlations were found among AVP, ACTH, CRF, SRIF and VIP. The correlation coefficients were similar for the three subject groups, with the exception of the correlation coefficient for CRF and VIP (see Table II). The strongly positive correlation between CRF and VIP in controls was not present among the bipolar patients, suggesting that the patients may have had a dysfunction of whatever regulatory mechanisms determine the levels of these two peptides in CSF. No significant correlations (defined as $P\leqslant0.05$) were found between CSF NT levels and any other peptide (data not shown).

Discussion

The most interesting finding in this study is the significant correlations among CSF neuropeptides. This deserves a comment on the origins of CSF neuropeptides.

Some hypothalamic neurons (that contain SRIF) have nerve endings at the wall of the third ventricle (Pollay M., 1979; Knigge *et al*, 1980). Several investigators have hypothesised that neuropeptides may be released into CSF from such periventricular neurons, to be transported to distant CNS sites of action (Pollay, 1979; Knigge *et al*, 1980; Post *et al*, 1982). As indicated in the review by Jackson (1981), peptides may gain access to CSF via diffusion from CNS interstitial fluid, from the periphery at sites

TABLE I

CSF neuropeptide levels[1] in euthymic bipolar patients and controls

Peptide	*Controls*	*Lithium-treated bipolar patients*	*Unmedicated bipolar patients*
Neurotensin	58.6±13 (25)	65.2±6.8 (19)	56.0±13 (11)

SRIF	36.3±16.4 (31)	32.3±15.6 (27)	39.8±15.1 (16)
CRF	33.0±11.9 (31)	29.8±12.9 (26)	31.8±13.7 (15)

1. Values are mean (pg/ml)±standard deviation. The number of observations is given in parentheses.

where the blood–brain barrier does not exist or by transport from the tanycyte median eminence, as well as by direct release from neurons into CSF. However, Wood's (1982) review states that peripheral sources of CSF peptides are unlikely. Thus, it seems more probable that peptides reach CSF either through random diffusion or direct neuronal release.

Do the observed significant correlations favour direct release or random diffusions as the point of entry of neuropeptides into CSF? These correlations do not provide strong evidence favouring either hypothesis. However, these significant correlations are more congruous with the hypothesis that the concentrations of CRF, SRIF, AVP, VIP and ACTH in CSF are not the result of random simple diffusion from the interstitial space of the neurons of origin, because differences in number and activity of the various peptidergic neurons and their distance from the ventricular space would affect the process of random diffusion, and one would be less likely to observe significant correlations between numerous peptides (Berrettini *et al*, 1985*a*).

One possible explanation for the correlations between SRIF, AVP, VIP, CRF and ACTH in CSF may be that they are released from neurons into CSF in response to a stimulus. From their sites of release, they may be transported to distant CNS sites where each of them may mediate some aspect of the response to that stimulus. What evidence exists for stimulus-induced changes in these CSF peptides? Koob & Britton (1984) have shown that random inescapable footshock causes a doubling in rat CSF CRF, a response which is attenuated by diazepam. CSF, ACTH and β-endorphin levels increase several-fold following periaqueductal grey (but not internal capsule) self-stimulation for analgesia (Hosobuchi & Bloom, 1983). These studies suggest that certain stimuli can increase CSF levels of these peptides. Shared mechanisms of release into CSF may account for these correlations.

Other possible explanations for these correlations include shared catabolism by peptidases in CSF and shared transport out of CSF, but no evidence exists to support either of these possibilities.

Rubinow *et al* (1985) have reported that carbamazepine, which is an effective acute and prophylactic treatment for manic-depressive illness (Okuma *et al*, 1973; Post *et al*, 1983), decreases CSF SRIF levels. Because carbamazepine seems to have a therapeutic effect in the treatment of manic-depressive illness which is similar to that of lithium, we hypothesised that lithium might have a similar effect on CSF SRIF. This was clearly not the case in our data. Our results support those of Rubinow *et al* (1983), who reported that recovered patients did not show significantly decreased CSF SRIF levels, as was found among the acutely depressed patients. Thus, the lower CSF SRIF level is a state-dependent marker for depression.

Given that lithium antagonises the effects of AVP (Forrest, 1979) at a post-receptor site in the kidney, we hypothesised that lithium might cause increased presynaptic release of AVP in the CNS, yielding a higher CSF AVP level. There was no effect of lithium on CSF AVP, but we cannot exclude the possibility that lithium may alter CNS AVP activity without affecting CSF AVP levels.

Recent data show that CSF ACTH and CSF CRF levels are not abnormal in acutely depressed patients (Davis *et al*, 1984; Roy *et al*, in press), although Nemeroff *et al* (1984) found higher CSF CRF in acutely depressed patients. Thus, although evidence for abnormal pituitary ACTH regulation in acutely depressed patients has been reported by Gold *et al* (1984), CRF or ACTH levels in CSF do not appear to be affected. These observations are consistent with the hypothesis that CSF levels of these HPA-axis-related peptides are regulated independently of HPA axis function.

CSF levels of VIP and NT do not provide evidence for a trait disturbance of cholinergic function in affective illness. The fact that the bipolar group does not show a significant positive correlation between

CRF and VIP may reflect a disturbance of some regulatory factor that controls the release of CRF and VIP into CSF. Whether this is related to a trait disturbance of central cholinergic neurons in affective disorder must await further study. This connection seems possible in light of recent evidence that cholinergic agonists increase CSF VIP (Kaji *et al*, 1983).

Gjerris *et al* (1984) reported decreased CSF VIP levels in atypically depressed patients. They rated their patients atypical, using the Newcastle Rating Scale. While our patients were not rated with this scale, we believe that they are not atypical. Thus, our results in a euthymic population may be in agreement with those of Gjerris *et al* (1984), who found normal CSF VIP levels in their endogenously depressed patients.

The trend for lithium to reduce CSF VIP levels must be interpreted with caution, as it is of borderline significance. We have reported elsewhere similar results in plasma and an effect of lithium to increase the affinity of a lymphocyte VIP receptor for its ligand (Berrettini *et al*, 1985*b*). Whether this effect of lithium on VIP function is related to the efficacy of that ion in affective illness must await further study. The levels reported here for CSF VIP are somewhat lower than previously reported by us (Berrettini *et al*, 1985*b*). This may represent slight changes in antibody specificity. (The antibody is from a commercial source.)

That CSF NT levels are not correlated with those of any other CSF peptide suggests that CSF NT levels are relatively independent of whatever factors generate the correlations between the CSF levels of CRF, ACTH, VIP, SRIF and AVP. This statement is limited by the difficulty in drawing conclusions about the absence of a significant correlation.

In summary, we find no evidence in bipolar affective illness for a trait disturbance of CSF, SRIF, ACTH, CRF, AVP, VIP or NT. It is unknown to what extent CSF levels of these neuropeptides reflect CNS activity of the peptidergic neurons in question. CSF levels of ACTH, CRF, SRIF, AVP and VIP are positively correlated with one another, suggesting that they share a common regulatory factor which determines CSF levels. Lastly, some evidence has been obtained suggesting that the functional relationship of CRF and VIP in CSF is disturbed in euthymic bipolar patients.

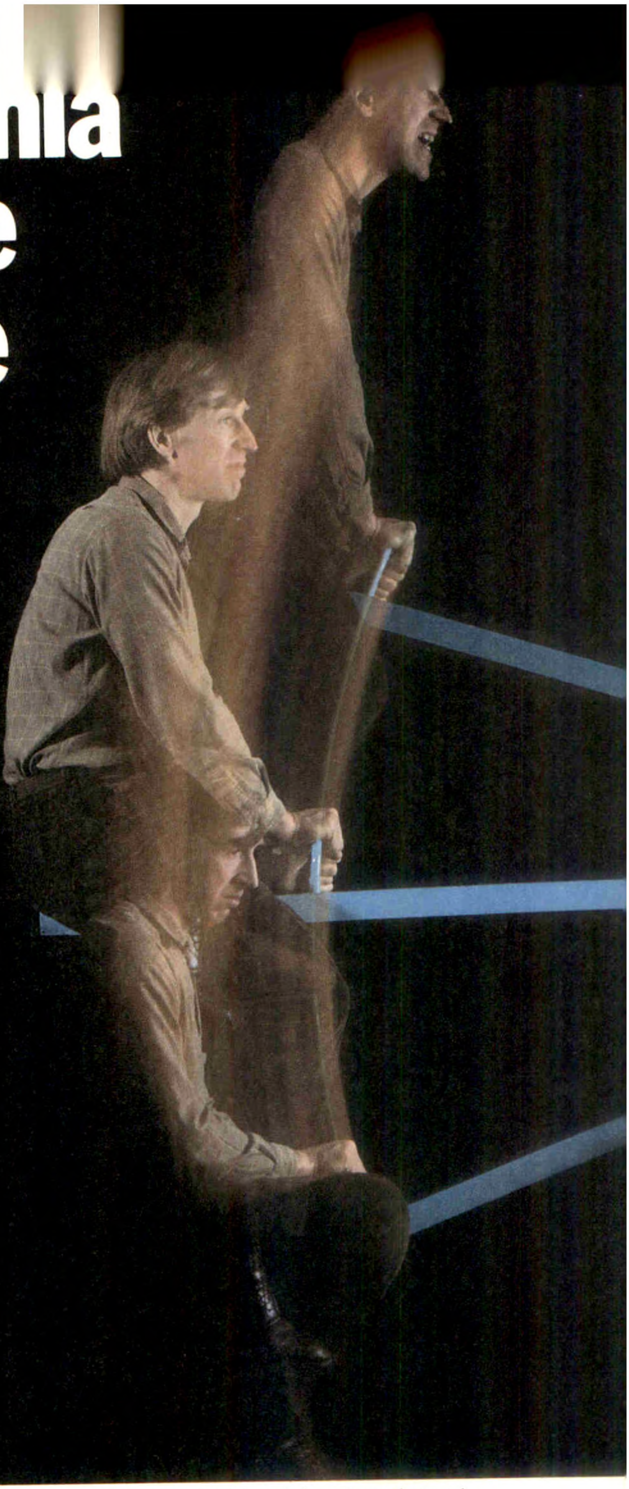
Schizophrenia therapy: the importance of balance



Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets his critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.[1]

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,[2-5] and because injections need only be given every four weeks, patients hardly know they are being treated.

Piportil
DEPOT PIPOTHIAZINE PALMITATE

Piportil Depot Prescribing Information
Dosage: *(Adults)* Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg (1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, severe cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, depression, blurred vision, asthenia, impotence, dry mouth, nausea, amenorrhoea, galactorrhoea, hypotension, hyperhydrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08½ ampoules (PL0012/0117). **References:** 1. A SCHIZOPHRENIC.

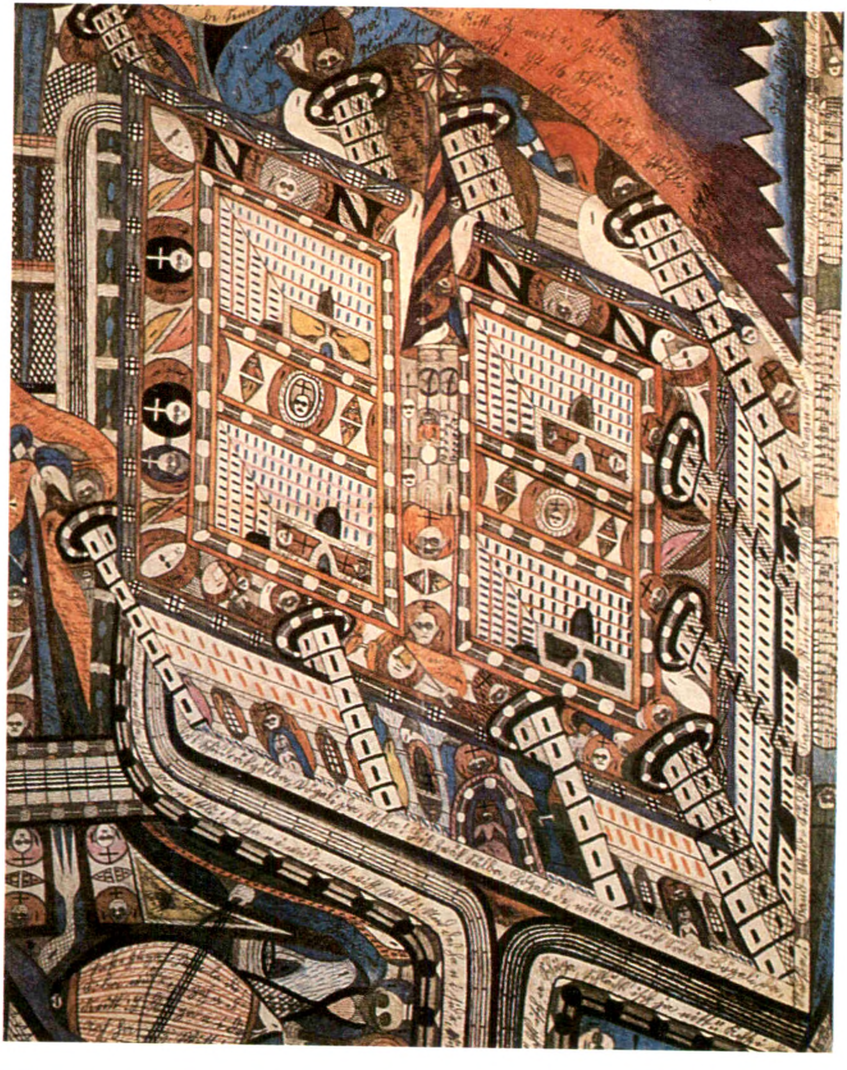
Adolf Wölfli spent 35 years in the Waldau Mental Hospital, Berne, suffering from schizophrenia. During that time he produced many drawings that have since gained widespread acclaim.

The picture below is one of a number that, we believe, give an insight into the schizophrenic mind and is reproduced with the kind permission of the Museum of Fine Art, Berne.



A SOLUTION.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol it has become widely established throughout the world as an effective antipsychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration following a single deep intramuscular injection.

Dosage is from 50–100mg in mild symptomatology whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation and a reduced requirement for antiparkinsonian medication, leaving him better able to participate in other forms of therapy.

100mg/ml

HALDOL*

haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

▼**Presentation:** Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses:** As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side-effects, precautions, contra-indications:** Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease. Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa, and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side Effects: In common with all neuroleptics, the following side effects may be observed: sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Rarely neuroleptic malignant syndrome has been reported. **Dosage:** Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. Dosage should be individually determined. As a guide: in mild symptomatology and in the elderly 50-100mg every 4 weeks; in moderate symptomatology 100-200mg every 4 weeks; in severe symptomatology 200-300mg or more every 4 weeks. **Product Licence No:** PL0242/0095, PL0242/0094 **Basic NHS Cost:** 100mg/ml: 1ml x 5 £24.00; 50mg/ml: 1ml x 5 £15.60 (correct at time of printing). When depression is the source of anxiety...

PROTHIADEN

Dothiepin Hydrochloride B.P.

restores peace of mind

Differential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female patients will usually present with symptoms of both. The potential risks of an inappropriate choice of treatment for these patients can often be a cause for concern.

Prothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this concern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left untreated.

So, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well as that of your patients.

PRESCRIBING INFORMATION

Presentation: Prothiaden is Dothiepin Hydrochloride B.P. an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 75mg £4.00 as at 1st Nov. 1986. **Product Licence Numbers:** PL0014/5941. PL0014/0209. The Boots Company PLC, Nottingham, England. Further information available on request.

The Psychological Effects of Service in British Antarctica:
A Study Using the General Health Questionnaire

J. BELL and P. H. GARTHWAITE

This study follows the psychological profile of a group of Antarctic explorers on a remote base in British Antarctica. Each month for 1 year the 60-item General Health Questionnaire (GHQ) was administered to the 12-man complement and the results compared to those of a control group. Three men resigned and left, 4 months later, at the end of winter. Their scoring showed marked differences from the others, including the highest scores in the severe depression factor scale. The GHQ was accepted by the men despite the intrusive threat it offered in such a small community; there was also a seasonal variation in scoring, with higher scores in the winter, and no evidence of long-term psychological sequelae in those who stayed.

The present Antarctic treaty lapses in 1991 and, as this date approaches, international interest in the continent is gathering momentum. Several studies report the occurrence of psychological disturbances in the Antarctic (Mullin & Connery, 1959; Strange & Klein, 1973; de Monchaux *et al*, 1979; Bell, 1984). That such morbidity should occur is not surprising: the Antarctic is a harsh, alien environment that is both isolated and dangerous. It is likely that as populations there increase, so will the numbers of psychological problems.

This paper reports a study that followed the psychological profile of a small group of workers in the Antarctic over the course of a year. The study was conducted at Rothera Station, a scientific base in British Antarctica, where one of the authors (J.B.) served as medical officer. In the study, the instrument used to quantify people's psychological state was the General Health Questionnaire (GHQ) designed by Goldberg (1972). This questionnaire has been used and validated in a variety of cultures and settings, including Jamaica (Harding, 1976), Australia (Worsley *et al*, 1978), Spain (Munoz *et al*, 1978) and Yugoslavia (Radovanovic & Eric, 1983), but to the writers' knowledge it has not previously been used in Antarctica.

The study started in April 1983, at the beginning of the Antarctic winter, and continued until March 1984. The GHQ was administered monthly to the 12 base members who were spending the winter on Rothera base and who were all volunteers. Three of them resigned prematurely in mid-winter and left the Antarctic, 7 months after the study started, when the base was relieved. They were replaced in the study by three members of the relief party.

The study's main aim was to examine the psychological changes that occur in men during their stay in Antarctica and also to examine the usefulness of the GHQ in an Antarctic setting. We paid particular attention to the three men who resigned prematurely, two of whom were diagnosed as psychologically disturbed. We found that their psychological states, as measured by GHQ scores, showed some marked differences from those of the people who did not resign. The seasons have a dominating influence on Antarctic life and so we also compared winter and summer GHQ scores. We found them to be generally higher in winter, when there was a greater incidence of sleep disturbance and general illness. However, if one excludes from consideration those people who were anxious to leave the Antarctic, our study then gives no indication that spending the winter there has any residual effect on a person's mental health in the following summer.

As part of the study, the GHQ was also administered to a control group of 21 men living in a conventional urban setting. Their scores were compared with those of the people in the Antarctic who did not resign but, perhaps surprisingly, few differences between these two groups were found.

It is clearly to an individual's detriment to remain in the Antarctic when suffering psychological morbidity. Not only are facilities for treating him on a small remote base inadequate, but the Antarctic itself is often the root cause of the psychological problems, and leaving often appears to serve as both treatment and cure. The rigorous climatic conditions of the Antarctic preclude evacuation during the winter. Therefore, one long-term aim of psychological studies in the Antarctic must be to develop methods of detecting very early signs of psychological disturbance and identify precursor factors of psychological morbidity. As questionnaires such as the GHQ are so straightforward to administer, their usefulness for predicting psychological morbidity is of obvious interest. Our study tentatively suggests that the GHQ may be of some value in this area.

Method

Rothera Base

Rothera Station is the main earth sciences base of the British Antarctic Survey. It lies just inside the Antarctic circle on Adelaide Island, off the west coast of the Antarctic peninsula, about 900 miles due south of Cape Horn. The year there divides into two distinct phases—winter and summer. The winter phase lasts about 7 months, beginning with the departure of the aeroplanes and relief ship at the end of March. Winter isolates the party of 12 men on the base and brings progressively shorter days, colder temperatures and more violent storms. The base is warm and comfortable, but there are essential tasks such as gathering ice-blocks for water, feeding the dogs and shifting fuel drums, which must be carried out regardless of the weather. Each man chooses his own pace of life, which varies from a busy routine of hobbies and work for some, to long periods alternating between the bunk and the bar for others. Generally, the group maintained good relationships with one another, although minor groupings did form and there were occasional signs of stress between individuals. (A full analysis of the social structure of the base is beyond the scope of this paper.)

The summer phase starts in late October when aeroplanes arrive, ferrying in men and equipment at spring relief. The days are long and the weather often perfect for many weeks. The base complement swells to over 40 and it is a time of busy activity, supporting scientific missions and summer bases scattered over the Antarctic peninsula. There is a consistently high pressure of work that only ends in March, when the ship arrives, autumn relief takes place and the winter phase starts again.

General Health Questionnaire

The standard 60-item version of the GHQ was used. The relationship between all 60 questions and factor scales is unclear from earlier studies. As suggested by Goldberg (1978), we discarded 30 of them when examining different symptoms and used the remainder to form six factor scales of five questions each: general illness, somatic symptoms, sleep disturbance, social dysfunction, anxiety and dysphoria, and severe depression. The scales proved to be of particular use in illuminating the different scoring patterns of individuals. Responses to the GHQ were evaluated using the Likert scoring system (a progressive scale that gives each column a score of 0, 1, 2 or 3).

The Antarctic group

During the study, the GHQ was administered to subjects at the beginning of each month. This was done early in the morning, immediately after other physiological and medical data had been gathered as part of a medical research programme. The setting for answering the questionnaire was made as consultative as possible. Subjects filled in the form at their own pace, alone and undisturbed. None of them said they found the routine time-consuming, stressful or overly intrusive. Some subjects were absent from base for parts of the summer and did not answer the GHQ every month; thus, there were 10 missing records from a total of 144. The ages of the 12 participants over the winter period ranged from 23 to 38, and averaged 28.6 years. The three subjects who resigned were aged 22, 26 and 32 and were replaced by men aged 34, 33 and 37 years.

The control group

To allow a comparison between the Antarctic group and men in urban surroundings, a control group of 21 men was drawn from staff at the medical school of Aberdeen. They were chosen to be of similar age to the Antarctic group (their ages ranged from 22 to 39) but the only other selection criterion was their willingness to participate in the study. Unlike the Antarctic group, who were all single, eight of them were married. The GHQ was administered individually to each of them once. They completed it in a setting that was quiet and consultative, although the location and time of day varied from person to person.

Clinical diagnosis

Two men were diagnosed as having a degree of psychological disorder that was of clinical significance. These were confirmed for their 'caseness' by submission of their case histories to four independent consultant psychiatrists in Aberdeen, who concurred with the diagnoses.

Statistical analysis

Unpaired t-tests were used to compare the Likert scores of different groups of people and paired t-tests used to compare the scores of a single group of people over two different time periods. The three people who resigned early did not form a homogeneous group, so their scores were examined individually. For each factor scale their scores were compared to the scores of the nine people who were with them in the Antarctic and did not resign. As a measure of the differences between an individual's score and the mean score of this group, we quote the number of standard deviations (s.d.s) by which the individual's score exceeds the mean. (Standard deviations were estimated from the scores of non-resigners.) If scores were normally distributed, then a difference of 2.43 s.d.s would equate to a significance level of $P=0.05$, 3.54 s.d.s to $P=0.01$ and 5.31 s.d.s to $P=0.001$. However, scores did not follow normal distributions precisely, so we used these values only as a guide (we will not quote significance levels when discussing individuals) and are cautious in the conclusions we draw.

TABLE I

Monthly Likert scores on the 60-item GHQ

Scores above or equal to the threshold level of 40 are given in **bold type**.

Results

Monthly Likert scores on the 60-item GHQ are given for each individual in Table I. Goldberg (1972) suggested a cutting score of 40 and above as suggestive of psychological disturbance. This seemed a reasonable threshold to use in the Antarctic as, if one ignored isolated high scores, then no false positives were found and only one false negative. Scores above or equal to the threshold level of 40 are given in bold type in the table. Of the three men who resigned early, two of them (A and B) had many monthly scores above the threshold. A's were above it every month, while B's only fell below it in his last 2 months on the base, after his resignation had been accepted and he knew he would soon be leaving the Antarctic. Their high scores in April, at the start of winter, preceded their decisions to resign by 3 months. Of the other men, most had one or more scores above the threshold during the last two-thirds of the winter (June–October). Otherwise, the only time scores went above the threshold was in February and March when D, E and H, who were all scheduled to leave the Antarctic at the end of March, had at least one high score.

People resigning early

The men who resigned early (subjects A, B and C) participated in only the first 7 months of the study. Table II gives the average score over this period for each person on the six factor scales. The three resigners had the three highest scores on the severe depression scale ($P<0.005$). However, on the other scales their scores did not show the same degree of homogeneity, so we examined their scores individually.

Subject A was diagnosed as having an anxiety-depressive state which gradually developed over the winter. He was still receiving psychological treatment 1 year after

TABLE II

Average Likert scores over the winter period by factor scale

	Factor scale					
Subject	*General illness*	*Somatic symptoms*	*Sleep disturbance*	*Social dysfunction*	*Anxiety and dysphoria*	*Severe depression*
A	7.86	0.71	1.29	6.29	10.29	3.14
B	7.29	2.86	5.14	4.86	4.14	1.29
C	2.43	0.15	0	5.00	0.29	1.71
D	4.71	1.29	2.43	4.86	0.86	0
E	4.71	0	3.86	5.43	0.86	0
F	2.71	0.29	2.71	5.14	1.71	0.43
G	3.43	0	3.86	4.14	1.29	0
H	6.43	0.71	7.57	4.57	1.00	0
I	2.57	1.00	2.57	4.57	0	0
J	3.43	0.14	3.29	3.00	0.71	0.71
K	2.29	0.29	1.43	5.00	0	0
L	2.57	0	0.86	4.86	0	0

leaving the Antarctic. On four of the six factor scales, his average score was higher than that of anyone else. It was exceptionally high on the anxiety and dysphoria scale (15.7 s.d.s above the average of the nine winterers who did not resign) and on the severe depression scale (11.5 s.d.s above average). The other scales where his average score was the highest were general illness (3.1 s.d.s above average) and social dysfunction (2.3 s.d.s above average).

Subject B was not clinically disturbed but was clearly unhappy being in the Antarctic. He had particularly high scores on the scales of anxiety and dysphoria and somatic symptoms (5.6 and 5.1 s.d.s above average respectively). On the latter scale, his average was more than twice as large as anyone else's. His score was also noticeably above average on the scale severe depression (4.4 s.d.s above average).

Subject C was diagnosed as suffering a depressive neurosis with associated personality disorder and adjustment reaction. He was always somewhat distrustful of the questionnaire and the motives behind its administration. His state was chronic rather than acute (personal observation) and did not change much over the winter. His scores tended to be lower than average rather than higher; for example, he was the only person to show consistently no signs of sleep disturbances. It is possible he was not altogether honest in his answers to the questionnaire. Tennant (1977) found that false negatives with the GHQ were often defensive individuals who used denial as a means of coping. On the other hand, the chronicity of his state may have been the basis of his low scores: the limitations of the GHQ in chronic disorders have been recognised in other studies (Finlay-Jones & Murphy, 1979; Goodchild & Duncan-Jones, 1985). The only scale on which he did score highly was for severe depression (6.1 s.d.s above average).

Winter *vs* summer

We refer to the nine men who participated in the study over both the winter and summer as the 'winterers' group. For every factor scale their overall average was lower in the summer than in the winter. The proportional reduction was particularly large for the sleep disturbance scale where the average score in summer was less than half the value in winter. Paired *t*-tests showed there was some evidence that individuals' average scores were lower in summer than winter on the scales general illness ($t = 2.48$, $P < 0.05$) and sleep disturbances ($t = 2.70$, $P < 0.05$). On the other four scales, the differences between summer and winter scores were not significant ($t < 1.63$, $P > 0.10$), but the total scores over the full 60-item questionnaire were significantly lower in summer ($t = 3.05$, $P < 0.02$).

Residual effect of winter on subsequent scores in summer

The base personnel in the Antarctic over the summer consisted of the group of nine winterers and another group of three people who arrived at the start of summer. The scores over the summer of these two groups were compared but no evidence was found of a difference between them on any factor scale (unpaired *t*-tests were used to make these comparisons; the largest *t*-value found was 0.84, $P > 0.1$). Hence, there is no suggestion that wintering in the Antarctic has a residual effect on those who are content to stay.

Comparison of the control group

If one excludes the three people who resigned, then over the winter the average scores of the people in Antarctica were lower than those of the control group on half the factor scales and, over the summer, their average scores were lower than those of the control group on all factor scales apart from social dysfunction. However, the differences were all small and none was statistically significant ($t < 1.98$, $P > 0.05$).

Discussion

In our study, we found distinct differences between the three men who resigned prematurely and the men who did not. We first summarise our findings on the latter, who formed a more homogeneous group. In general, they had low scores in both summer and winter on the factor scales—somatic symptoms, anxiety and dysphoria, and severe depression. Their scores were much higher on the other factor scales—social dysfunction, general illness and sleep disturbance, and on the last two of these there is a detectable seasonal difference, with higher scores in winter. The difference is particularly marked on the sleep disturbance scale, where the winter average score was twice that of summer. However, over the summer, there was no apparent difference between the men who arrived in the Antarctic at the start of summer and those who had spent the winter there, suggesting that the Antarctic winter had no lasting effect on them. A comparison of the scores over the summer with those of a control group supports this view: on five of the six factor scales the group in the Antarctic had lower average scores than the control group, although the differences were small. Over the winter, their scores tended to be only slightly higher than the control group, although most had scores on the 60-item GHQ that were above the threshold of 39 in 1 or 2 months. Despite these occasional high scores, it seems that there is no evidence of long-term psychological disturbance in the initially well-adjusted.

These findings are essentially in agreement with those of other studies. Mullin (1960) found no evidence of adverse change in individuals with experience of the Antarctic; Law (1960) found that men were generally positive about their experience, variously stating that it had made them more tolerant, better controlled, more adaptable and more confident. It is worth noting that these studies examined people who had returned (or were on the point of returning) from the Antarctic, while our study suggests that most people are psychologically well for almost all the time they are there. Several people have also found a greater incidence of psychological disturbance over winter—the so-called 'wintering-over' syndrome (Strange & Klein, 1973). Other studies do not comment on the precise symptoms found in our factor scales but the prevalence of sleep disturbance is well documented (Lewis & Masterson, 1957; Natani & Shurley, 1973). We found that subjects were troubled by sleep disturbance in winter, but less so in summer.

These findings do not apply to the three people who resigned prematurely. Turning our attention to them, we find that their psychological health was disturbed by being in the Antarctic. One was clearly unhappy being there and the other two were clinically diagnosed as psychologically ill. One of these latter was still receiving psychiatric help a year after leaving the Antarctic. (Fortunately, this is a comparatively rare occurrence; other studies indicate that any harmful effects from living in the Antarctic usually disappear on return to a more normal environment [Taylor, 1978]). Whether their psychological difficulties were exaggerated by the 'wintering-over syndrome' is a matter for conjecture, but the fact that they resigned in winter rather than in summer is perhaps what one might expect.

The Likert scores of the three people who resigned show clear differences from those of the others. They have the three highest scores on the severe depression factor scale, as well as all the high scores on the somatic symptoms and anxiety and dysphoria scales. Thus, there is the suggestion that a high score on one or more of these scales is indicative that a person is suffering psychologically from being in the Antarctic. In contrast, high scores on the scales —general illness, social dysfunction or sleep disturbance appear to carry no such portent. Other studies have reported that depression (Strange & Klein, 1973) and somatic symptoms (Palmai, 1963) are a common problem in Antarctica. Our findings suggest that these symptoms (and also anxiety and dysphoria) are confined to a relatively small proportion of the people there and do not affect the majority.

The GHQ was not designed for use in the Antarctic but appears to have performed very well in that setting. It is true that only two of the three people who resigned had high scores on the 60-item GHQ, but they both had scores that were almost always well above the threshold of 39. Moreover, in the first month of the study, which was also the first month of winter, their scores of 59 and 73 were well above the threshold, while the next highest score of 34 was below it. This suggests that the GHQ might be useful for predicting at the onset of winter which people are likely to suffer psychologically during its course. In making predictions, the questions on the GHQ should perhaps not be scored equally. Our earlier findings suggest more emphasis should be placed on the factor scales—somatic symptoms, anxiety and dysphoria and, in particular, severe depression.

The study shows that questionnaires such as the GHQ can be used to follow the psychological profile of men while they are in the Antarctic. People proved willing to answer it and were prepared to do so repeatedly. This latter is important, since many individuals seem occasionally to give isolated high scores that have no long-term significance. In the main, people seem to have given honest answers to the questionnaire and these appear to reflect their psychological state. The number of people examined in the study is small but this will inevitably be the case with studies in the Antarctic. For progress to be made in understanding the psychological problems that occur there, other similar studies need to be conducted in an organised fashion and their results pooled to yield a more complete picture than a single study.

Acknowledgements

We wish to extend our thanks to Professor G. Ashcroft of the Department of Mental Health, University of Aberdeen, Professor D. Goldberg of the Department of Psychiatry, University Hospital South Manchester, and Professor K. Rawnsley of the Department of Psychological Medicine, University of Wales, College of Medicine, for their invaluable advice during the preparation of this paper.

JOIN YOUR COLLEAGUES IN AUSTRALIA AT

THE NINTH WORLD CONGRESS OF THE INTERNATIONAL COLLEGE OF PSYCHOSOMATIC MEDICINE TO BE HELD IN SYDNEY, AUSTRALIA AUGUST 30TH TO SEPTEMBER 4TH, 1987.

The Congress will be held at the Sydney Hilton Hotel and will involve specialist seminars, free paper sessions and workshops encompassing a wide range of psychomatic topics. The Organizing Committee is keen to establish an environment which encourages wide discussion among the participants. Keynote addresses will be presented by a number of eminent workers in our field including Dr L. Levi (Stockholm), Dr R. Rosenman (San Francisco), Dr H. Moldofsky (Toronto), Dr G. Schwartz (New Haven), Dr D. Goldberg (Manchester), Dr Z. Lipowski (Dartmouth), Dr C. Cooper (Manchester), Dr D. Garner (Toronto) and Dr R. Rubin (Los Angeles). The meeting is held under the auspices of the Royal Australian New Zealand College of Psychiatrists, The Royal Australian College of General Practitioners and the Australian Psychological Society. We in Australia look forward to welcoming you with us.

Aspects of Epilepsy and Psychiatry
Edited by MICHAEL A. TRIMBLE and TOM G. BOLWIG

From the growing interest in the relationship between epilepsy and psychiatry, two main areas emerge. First is the academic debate as to whether or not psychopathology is interlinked with the biological processes of epilepsy and, secondly, how should we manage at a clinical level the cognitive and behavioural disturbances which arise in epileptic patients? With broad emphasis on these two themes, this book presents some of the more controversial and less well documented aspects of this disease.

Influence of Emotional Distress among Supporters on the Outcome of Psychogeriatric Day Care

C. J. GILLEARD

From a sample of consecutive referrals for psychogeriatric day care, the influence of the supporters' emotional distress and self-reported strain, together with the number of problems presented by the patient, was examined in relation to outcome, 6–7 months after initial attendance. A higher level of problems and the failure to achieve any reduction in reported distress were both found to contribute to the breakdown of community care and to the subsequent institutionalisation of the patient. Day hospital care was associated with a significant reduction in emotional distress for the majority of relatives, although for relatives whose distress was not alleviated by their dependents' attendance, admission to long-term care did produce such a reduction.

One of the most frequently cited goals of psychogeriatric day hospitals is the relief of strain amongst relatives caring for the elderly patient (Greene & Timbury, 1979; Peace, 1982; Sands & Suzuki, 1983). The high level of emotional distress and strain experienced by supporting relatives of patients newly referred to psychogeriatric day care has been described in an earlier paper (Gilleard *et al*, 1984*a*). We found that much of this distress could be accounted directly for by the problems experienced by the supporter in caring for their mentally infirm relative. The present study was undertaken to examine the significance of the supporters' strain and distress in determining the outcome of psychogeriatric day care, and in particular the breakdown of the assisted community care afforded by day hospitals. The principal hypothesis to be tested is that the level of strain experienced by supporters contributes directly to the breakdown of community care, and that day hospital services are effective in keeping the elderly person at home when they serve to reduce that distress. Some support already exists for this hypothesis. Levin *et al* (1983) have demonstrated a significant relationship between distress levels in supporters of confused elderly people and subsequent institutionalisation of the dependents.

However, since supporters' strain and distress are closely linked to the nature and number of behaviour problems presented by their dependent (Greene *et al*, 1982; Gilleard *et al*, 1984*a*), it may be the problems themselves which principally determine the supporters' ability to continue to care. In this case, day hospital services will only be effective in keeping the elderly person at home when they serve to reduce the frequency of the problems presented to the supporter at home. Distress and strain will only appear to be influential in determining outcome in so far as they are reflecting the problems currently faced by supporters.

Retrospective studies (e.g. Isaacs, 1971) which identify family strain as a cause of institutional care are less helpful in answering such questions, since they cannot easily unravel the interdependent influences of strain and stressors. It seems desirable to examine the process of breakdown in care through prospective studies, where the relative influences of strains and stressors can be linked to future outcomes. The prospective study of community referrals for psychogeriatric day care from which the present data were obtained offered such an opportunity.

Method

Sample

The present sample was formed by 129 community referrals for psychogeriatric day hospital care to four such units in the Lothian region of Scotland. Each of the supporters was interviewed at the point when they had been offered day care for their relative, and again 3 and 6–7 months later. Details of these patient–supporter pairs have been described elsewhere (Gilleard *et al*, 1984*b*): briefly, all but 18 had a clinical diagnosis of dementia, all were living in the community and were looked after by a relative who either lived with them ($n = 90$) or visited at least three times per week ($n = 39$).

Measures

The interview and questionnaires were also described in the previous paper (Gilleard *et al*, 1984*b*). The chief measures analysed here were the 28-item Problem Checklist—covering the reported frequency of such behaviour problems as incontinence, mobility, disturbed behaviour, excessive demands, impairments in self-care and forgetfulness; the 30-item General Health Questionnaire (GHQ) (Goldberg, 1978) as an index of emotional distress; and a 13-item measure of strain derived from Machin's (1980) Strain Scale, modified to a three- rather than a five-point response format. The high internal reliability of the Problem Checklist total score has been reported in a separate study (Eagles & Gilleard, 1984), while the internal reliability and external validity of the Strain Scale have been documented by Machin. The minor modifications made to this scale (*vide* Appendix) do not appear to have reduced its internal consistency (internal reliability alpha coefficient = 0.87).

Outcome categories

To test the hypothesis, three categories of outcome were examined: those who attended day hospital consistently over the 6–7 month follow-up; those who ceased attendance before the end of the follow-up, but continued to be looked after at home by their relative; and those who attended for at least 3 months, but were admitted to long-term institutional care before the end of the follow-up period. Excluded from this analysis were those whose dependent died ($n = 13$), whose dependent entered institutional care less than 3 months after starting at the day hospital ($n = 19$), whose dependent never attended day hospital ($n = 4$), and an additional eight supporters who could not be interviewed at the 3-month follow-up.

Of the remaining 86 supporters eligible for this study, 36 had their dependent still attending day hospital (complete data, $n = 29$), 23 were looking after their dependent at home, but the patient had stopped attending (complete data, $n = 20$), and 26 had had their dependent admitted for long-term care (complete data, $n = 18$). The 19 supporters with some missing data had in most cases failed to respond to some of the items in the questionnaires.

Results

Table I presents the original scores of the total 'potential' sample, together with those from the sample with complete 3-month follow-up data. None of the means of this latter group deviated by more than 1 s.e. from those established for the original 'potential' sample, and it seems reasonable to conclude that the 'complete data' sample is not a significantly biased subsample.

The next stage in the analysis was to examine the differences between the three outcome groups in the level of problems faced, and in the strain and distress experienced during the first 3 months of day hospital attendance. Three univariate repeated measures analyses of variance were run using the SPSS MANOVA programme (SPSS, 1983). The means and standard deviations on both occasions are presented in Table II, together with the F values obtained for the group, occasion and group × occasion effects. No significant differences in the within-cell variances were observed.

The largest group differences were observed on the Problem Checklist scores. Those patients who were eventually admitted to long-term care presented a significantly higher number of problems throughout the first 3 months of day hospital attendance than did those who remained in the community. However, no group showed any evidence of a significant increase in the problems reported by their relatives. The results for the Strain Scale showed a similar, but less pronounced pattern. The supporters' GHQ scores showed a different pattern, with no outcome group differences but a highly significant decline over the first 3 months. It appears that day hospital care does reduce emotional distress amongst supporters, while having no obvious impact on the problems presented by the patients. The groups × occasions interaction term is not at a conventional level of significance ($P = 0.06$), but there is a clear suggestion that those supporters whose dependent will later be admitted for long-term care do not experience any reduction in their distress, unlike those whose dependent continues to attend day care for at least a further 3 or 4 months, whose GHQ score almost halved at the 3-month follow-up.

Since problems correlate closely with both measures of strain and distress—in this sample, the overall correlations for initial scores were 0.64 (Problem Checklist and Strain Scale) and 0.56 (Problem Checklist and GHQ)—a further analysis was conducted to examine the outcome group differences in the strain and distress scales, partialling out the influence of the problems reported by the supporters on both occasions. Two repeated measures analyses of covariance were performed on the GHQ and Strain Scale scores. The results of this analysis indicated that GHQ

$^*P<0.05$; $^{**}P<0.01$.

scores showed an overall significant decline during the first 3 months ($F=19.7$; d.f. = 1, 63: $P<0.01$), with a now statistically significant interaction according to later outcome ($F=3.2$; d.f. = 2.63, $P<0.05$). There were no overall differences in GHQ scores by outcome group ($F=1.0$; d.f. = 2, 63; NS). As a result of partialling out the influence of the covariate, total problem score, no significant differences were evident between the three outcome groups on their adjusted scores on either initial or later interview point on the Strain Scale.

Finally, we examined changes over the full study period in the supporters' levels of distress, measured by the GHQ,

TABLE III
Changes in mean GHQ scores over the whole study period according to outcome circumstances and daycare attendance

	Initial *mean (s.d.)*	*3 months* *mean (s.d.)*	*6–7 months* *mean (s.d.)*
Attended throughout the study ($n=31$)	12.6 (7.7)	6.4 (6.9)	5.9 (8.2)
Discharged to own home after attendance ($n=17$)	7.6 (7.8)	4.9 (7.2)	5.2 (5.8)
Admitted to long-stay care after more than 3 months' attendance ($n=17$)	13.3 (6.4)	11.0 (8.3)	4.7 (6.4)
Admitted to long-stay care less than 3 months' attendance ($n=16$)	13.6 (8.1)	6.8 (8.7)	4.5 (7.3)

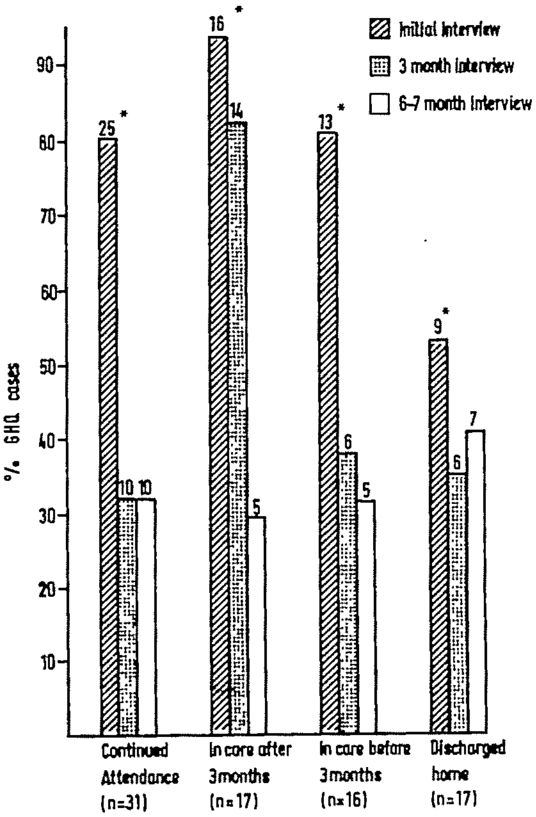

FIG. 1 Changes in relatives' GHQ caseness following day care and/or institutional admission of the patients. Numbers marked with an asterisk indicate the number of relatives scoring 5 and over on the GHQ (i.e. probable 'cases').

for all four outcome groups, including those ($n = 19$) whose dependent had been institutionalised. Since Strain Scale and Problem Checklist scores could only be obtained from supporters whose dependent was still at home, it was not appropriate to examine these variables over the full study period. Table III presents the means and standard deviations for each group on each occasion. Because some supporters had data missing from their final interview, the numbers in some groups are somewhat smaller than those in Table II, while other groups contain more subjects, since complete Problem Checklist and Strain Scale scores were not necessary for inclusion of subjects.

The results indicate significant differences in the development and remission of emotional distress amongst the supporters, depending upon the circumstances of their dependent. The main effect of outcome did not discriminate amongst the groups ($F = 1.28$; d.f. = 3, 77; NS), suggesting that the average level of supporters' distress was unrelated to the outcome situation of the patients. The occasions effect was significant ($F = 31.9$; d.f. = 2, 76, $P < 0.001$), with a large and significant overall decline during the first 3 months ($F = 62.4$; d.f. = 1, 77; $P < 0.001$) and a rather lower rate of decline over the last 3–4 months, though still significant ($F = 4.4$; d.f. = 1, 77; $P < 0.05$). A significant interaction term was observed ($F = 2.5$; d.f. = 6, 154; $P < 0.05$), although this was primarily due to the differential change during the first 3 months ($F = 3.3$; d.f. = 3, 77; $P < 0.05$), and not over the whole 6–7 months ($F = 1.6$; d.f. = 3, 77; NS).

If scores on the GHQ are treated as dichotomous rather than continuous variables, this effect can be seen even more clearly (Fig. 1). For this purpose, Goldberg's cut-off score on the GHQ of 5 and over was used to indicate 'probable caseness'. This sample of 81 supporters had, at the initial interview, an overall 'case' rate on the GHQ of 75%: this compares closely with 73.5% in the total ($n = 129$) sample. In every outcome group of supporters, apart from those whose dependent was later to be admitted to long-term care, the proportion of GHQ-defined cases dropped to less than 38% (i.e. halved) after the first 3 months; yet, amongst this latter group, the proportion of cases had hardly dropped at all—from 94 to 82%. By the time of the final follow-up, less than one-third of the relatives of patients still attending day care and a similar proportion of relatives whose dependents were in long-term care were still scoring as cases on the GHQ.

Discussion

While day hospital attendance produced no short-term reductions in the number of problems faced by the supporting relatives, it does seem to have significantly reduced their reported level of distress. Yet the 'strains' of caring remained unchanged. This differential response on the GHQ and Strain Scales may be understandable if the Strain Scale is seen as measuring the stressful experiences of caring, while the GHQ reflects the distress reaction within the carer. Thus, the former questionnaire asks "are you worried or depressed by, or unable to cope with your relative?", while the latter asks "are you worried, or depressed, or not able to cope?" The Strain Scale may therefore be an insensitive instrument to measure changes in the emotional effect of caring for an elderly mentally infirm relative.

Day hospital care and the relief it affords alleviated the more reactive emotional distress of the supporters; however, by not changing the problems presented by their dependents, the experience of caring may remain as much a strain as ever. The significance of reduced levels of distress appears to be that it permits carers to continue giving care, while the converse—a failure to reduce the supporter's distress—seems to predict the breakdown of care and resulting institutionalisation. This effect is quite independent of the level of problems faced by supporters. Of course, the level of problems itself has been demonstrated to influence outcome: those patients who present the most problems to their supporter are more likely to be institutionalised. But there is no evidence that an increase in the number of problems leads to the breakdown of care and subsequent institutionalisation.

Such findings offer considerable optimism concerning the potential of psychogeriatric day hospitals to contribute to the community care of the elderly mentally infirm. If institutionalisation was preventable only by decreasing the number of problems presented by the patient at home, then, to be effective in sustaining family care, day hospitals would have to both prevent the development of new and reduce the frequency of existing behavioural deficits and disturbances in a primarily dementing patient group—a task that is clearly daunting. That a reduction in distress, even in the absence of change in problems presented by the patient, is predictive of sustained community care suggests a much more attainable goal. Research directed at identifying those elements of care services most effective in reducing supporters' distress seems well worth pursuing, not only for the inherent value it offers the individual families, but also because it seems likely to lead to a reduction in the demand for the limited institutional resources available for the elderly mentally infirm, without adding to the burden on the family.

The findings which consider all four outcome groups also indicate that institutionalisation of the elderly mentally infirm does produce a significant reduction in level of emotional distress amongst care-giving relatives, but this effect is no greater than that achieved for more than two-thirds of those relatives whose dependent attended day hospital services for 3 months. In addition to investigations the means of reducing distress, it can be argued that we also need to know more about those whose distress day care fails to relieve, and whether or not for this group any real alternative exists to their relatives' admission into long-term care.

Acknowledgement

This study was funded by a grant from the Chief Scientist's Office, Scottish Home and Health Department.

Appendix

Strain Scale

Responses to each item are: 'a great deal of the time', 'sometimes' and 'never'. Scoring for item 9 is reversed.

(1) Do you fear accidents or dangers concerning the elderly person (e.g. fire, gas, falling over etc.)?
(2) Do you ever feel embarrassed by the elderly person in any way?
(3) Is your sleep ever interrupted by the elderly person?
(4) How often do you feel it is difficult to cope with the situation you are in and in particular with the elderly person?
(5) Do you ever get depressed about the situations?
(6) How much do you worry about the elderly person?
(7) Has your household routine been upset in caring for the elderly relative?
(8) Do you feel frustrated with your situation?
(9) Do you get any pleasure from caring for the elderly person?
(10) Do the problems of caring prevent you from getting away on holiday?
(11) Has your standard of living been affected in any way due to the necessity of caring for your elderly relative?
(12) Would you say that your health had suffered from looking after your relative?
(13) Do you find the demand for companionship and attention from the elderly person gets too much for you?

Plasma Levels of β-Endorphin in Depressed Patients
with and without Pain

R. J. DALY, P. F. DUGGAN, P. J. BRACKEN, H. J. DOONAN and N. J. KELLEHER

We studied 27 patients who complained of pain, for which no organic basis could be found, and 11 patients without pain. All patients were depressed according to clinical diagnosis and Beck Depression Inventory (BDI) scores. Plasma β-endorphin levels were found not to differ between the two groups or across other variables. The patients who complained of pain had significantly higher scores on the BDI.

Many patients complain of pain while suffering from depression (Merskey & Spear, 1967). However, investigations have demonstrated that some patients with affective disorders have diminished sensitivity to experimental pain stimuli (Davis, 1983). Psychological explanations were popular in the past for this association of altered pain sensitivity and affective illness but in recent years hypotheses based on biochemical research have been proposed. For example, Garvey *et al* (1983) showed that a group of patients who suffered from headaches during depressive episodes were younger, had more somatic complaints and experienced more hypersomnia than other depressives. They postulate that this association between depressive headaches and hypersomnia and somatic complaints might involve serotonin abnormalities. Since their discovery in 1975, much research has focussed on the endogenous opiates and their involvement in pain and mood disturbances.

Almay *et al* (1978) showed that in patients with pain, CSF β-endorphin levels correlated with patients' self-ratings of depression. Recently Atkinson *et al* (1983) studied plasma measures of β-endorphin in Chronic Pain Syndrome and psychiatric subjects. These authors found that the Chronic Pain patients demonstrated elevated concentrations of plasma β-endorphin immunoreactivity.

While it is possible that the endogenous opiates play a role in pain perception, it is still not clear if such a role can be identified with respect to affective illness. Some work has been successful in relating endorphins to the various other biological phenomena which are thought to be associated with depressive illness. In particular, studies have demonstrated a relationship with HPA (hypothalamic-pituitary-adrenal) axis activity. Rubinow *et al* (1981) found that CSF opioid activity related significantly to mean urinary-free cortisol in depressed patients but did not do so in controls. Cohen *et al* (1984) observed a relationship between levels of plasma β-endorphin imunoreactivity and levels of plasma cortisol in patients with major depression but not in those with minor depression or in controls. It has been shown that β-endorphin and ACTH are stored in the same secretory granules of the pituitary and are released together in animals during stress (Rossier *et al*, 1980). Mains *et al* (1977) showed that β-endorphin shared the same precursor molecule (pro-opiocortin) with ACTH. Plasma ACTH suppression after dexamethasone is accompanied by plasma opioid suppression (Kriegar & Liotta, 1979).

In spite of the emerging literature showing involvement of the HPA axis in depressive illness, research has not demonstrated a clear abnormality of endorphin measures in depression. Initial studies on CSF performed by Terenius *et al* (1977) showed elevated CSF opiate activity in depression; Naber *et al* (1981) could not replicate this and similarly Gerner & Sharp (1982) found no CSF endorphin abnormality in depressed patients. Plasma studies have also produced contrasting results. Brambilla *et al* (1981) found plasma β-endorphin levels which were significantly higher in patients with depression of both primary and secondary types. Risch (1982) also found significantly higher plasma β-endorphin immunoreactivity in a group of depressed patients meeting the Research Design Criteria (RDC) for Major Depressive Disorder or Schizo-affective Disorder–Depressed, than in a group of matched controls. Alexopoulos *et al* (1983) found no difference from normals. In a study by Cohen *et al* (1984), the plasma β-endorphin immunoreactivity was significantly lower in patients with non-major depression than in those with major depression or in normal subjects.

In the present study, the β-endorphin immunoreactivity was measured in a group of patients suffering from either Endogenous Depression (ICD

296.1) or Neurotic Depression (300.4). Also included were three patients who had a different ICD classification but were significantly depressed. Depressed mood was measured using the Beck Depression Inventory (Beck *et al*, 1961). Patients were divided into two groups: those complaining of pain and depression and those who were depressed but without pain.

Method

Subjects

Thirty-eight patients were studied. They were either in-patients or out-patients of the Professorial Psychiatric Unit at the Cork Regional Hospital. Twenty-seven patients were suffering from pain for which no organic basis could be found by appropriate investigation; they were also judged to be depressed by the referring psychiatrist. These patients complained mainly of headaches (17 patients), pains in the face and neck (2), abdomen (4), legs (2) and others (3). Their psychiatric diagnoses were as follows: neurotic depression (22) and endogenous depression (5).

A smaller group of 11 patients who stated that they had no pain were referred to the study. Their psychiatric diagnoses were as follows: neurotic depression (5), endogenous depression (3), personality disorder (1), anxiety state (1) and anorexia (1).

Twenty-two patients were receiving antidepressant medication at the time of the study.

Materials

On referral each patient was administered the BDI. Those who complained of pain were also administered a Visual Analogue Scale for pain (Ohnhaus & Adler, 1975). Blood was taken from patients on this occasion for plasma β-endorphin estimation. All samples were taken between 10–11.30 am. Blood (10 ml) was mixed with lithium heparin in a polypropylene tube which was stored on ice (no more than 15 min) until plasma was obtained by centrifugation at 3000 rpm for 10 min at 4°C. Samples were then frozen at −20°C.

β-Endorphin in plasma was measured by the RIA procedure marketed by the Immunonuclear Corporation. The specificity of the assay for β-endorphin was assured by removing cross-reacting β-lipotropin by affinity chromatography using a sepharose anti-β-endorphin complex. Only the elution peak containing β-endorphin was further processed. The radioimmunoassay involved overnight incubation of extracted samples with rabbit anti-β-endorphin and ^{125}I β-endorphin and phase separation was accomplished using goat anti-rabbit precipitating complex.

Statistics

For comparison of unpaired measurements as applied to unequal group sizes, the Mann Whitney U Test was used. Spearman's Rank Correlation Coefficient was used to assess correlation between two variables.

Results

See Table I and Table II.

Median β-endorphin level for group with pain = 6.0 pmol/litre. Median β-endorphin level for group without pain = 6.0 pmol/litre.

The results were analysed to see if there was any relationship between the demographic variables, sex and age, and endorphin levels, pain rating or BDI score. No statistically significant difference was found ($P>0.05$). Comparing those who were receiving antidepressant medication with those who were not, there was no significant difference in pain rating, endorphin level or BDI score ($P>0.05$). In those patients who complained of pain, no connection between pain scores and β-endorphin levels was found. When compared to the group of patients without pain, no significant difference in endorphin levels was found. However, a statistically significant difference in BDI scores was detected ($P<0.05$).

When all the BDI scores were compared with β-endorphin levels no significant correlation was found. When divided into diagnostic categories, i.e. Endogenous Depression *vs* Neurotic Depression and other Neuroses, no significant difference in β-endorphin levels was found.

Two of our patients had high outlying plasma β-endorphin values. One was an in-patient and we subsequently studied

TABLE III
Effect of ECT on plasma β-endorphin

	β-Endorphin concentration (pmol/litre)

4 h after convulsion	43	36	23

her plasma β-endorphin level while she had ECT (see Table III). The other patient was requested to have further studies but declined.

Discussion

Cohen *et al* (1984) found that plasma β-endorphin immunoreactivity was significantly lower in patients with non-major depression than in those with major depression or in normal subjects. In contrast to this, in our study of depressed patients without any diagnosed physical lesion, we found that plasma β-endorphin showed no difference in the subtypes of depression. However, our study group consisted predominantly of neurotic patients. Another difference was that in Cohen's study β-endorphin was not separated from β-lipotropin and the ratio between them was not determined. Brambilla *et al* (1981) found in their study of chronic schizophrenics that β-lipotropin and β-endorphin levels did not always increase in parallel and suggest that measuring both together might be misleading. Atkinson *et al* (1983), in a study of β-endorphin/β-lipotropin-like immunoreactivity in chronic pain syndrome and psychiatric subjects, found that pain patients had significantly higher β-endorphin/β-lipotropin-like immunoreactivity than psychiatric patients even though there was no significant difference in severity of depressive symptomatology. They state that "β-endorphin may reflect pain, stress or mood disturbance as a state or trait marker". Our results indicate no difference between depressed patients reporting pain and those without pain with regard to β-endorphin levels. There are some recognised limitations in using the Visual Analogue Scale to assess the difference in pain state between patients. In our study, β-endorphin level did not correlate with degree of pain, as measured on this scale. In a recent report, Willer *et al* (1984) present data which suggest that there is little correlation between plasma β-endorphin concentration and pain control in humans. The two patients who had high outlying values in our study (*viz* 72 and 30 pmol/litre) both complained of pain which is further evidence that plasma β-endorphin concentration and pain state are poorly correlated. We did find that the pain group scored higher on the BDI.

Much effort and research has been concentrated on β-endorphin over the past 10 years. A possible role has been elaborated for endorphins in psychiatric illness and in pain perception and in their association. If the state of β-endorphin metabolism is to be used as a viable state or trait marker for depressive illness it can be assumed that plasma would be the body fluid used. While presently it is accepted that CSF studies give a better indication of central β-endorphin metabolism (Woolf & Wall, 1983) there are serious limitations of an ethical nature to this line of research. Measures of β-endorphin may help to illuminate the role of HPA axis activity in depressive illness. However, our own study would indicate that a unitary measure of endorphin activity alone may not be sufficient to distinguish between subgroups of patients. In particular, we do not believe that β-endorphin levels can distinguish between those depressed patients with pain and those without pain.

Acknowledgements

The authors would like to acknowledge the assistance of Dr S. Martens in designing the protocol of the study and of Dr T. Cronin in referring patients suitable for inclusion in the study.

Reliability of the Psychosocial Axes of DSM-III in an Adolescent Population

J. M. REY, J. M. PLAPP, G. STEWART, I. RICHARDS and M. BASHIR

Three psychosocial variables were rated independently by two clinicians for 140 adolescent referrals to a psychiatric unit. Overall, intraclass correlations for DSM-III Axis IV, Axis V and a psychosocial adversity index (PSAI) were respectively 0.44, 0.58 and 0.68. The main source of unreliability is probably the operational definitions, rather than their application by clinicians; indices similar to the PSAI may be preferable.

Over the last decade, there has been a revival of interest in issues surrounding psychiatric diagnosis and classification: In the US, this resulted in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders*: DSM-III (American Psychiatric Association, 1980), while some European countries have produced a unified system of recording clinical data (AMDP) (Joint WHO/ADAMHA Project, 1983). Preliminary work is now being done to prepare the way for the mental disorders section of the tenth edition of the International Classification of Diseases (ICD-10). The most fundamental decision for ICD-10 is whether it is to be a multi-category single axis system like ICD-9, or a multi-axial system like DSM-III and (presumably) its successors. Against this background, it is surprising how little empirical work has been carried out on one of the most novel aspects of DSM-III—the psychosocial axes: Axis IV (severity of stressors) and Axis V (level of adaptive functioning).

The inclusion of separate axes for the recording of clinical ratings of psychosocial factors is a departure from previous practice which is at least as unusual as some of the other aspects of DSM-III that have received much more critical attention. Though there is agreement that psychosocial stress and premorbid functioning are particularly important variables, which may have aetiological or prognostic value (Rutter & Shaffer, 1980), it does not necessarily follow that their formal definition and incorporation as separate axes in each diagnosis is the best way to ensure that this information will be considered. Nor does it ensure that the data will be recorded, since 19% of Axis IV ratings and 11% of Axis V ratings were 'unspecified' in the 1111 multiaxial DSM-III diagnoses reported by Mezzich *et al* (1982).

In any case, the agreement about the importance of psychosocial factors does not extend to their operational definitions in DSM-III; Rutter & Shaffer (1980) indicated some of the problems with the current definitions, and Kendell (1983) predicted that 'radical alterations' would be needed if Axes IV and V were to survive. The widespread acceptance of DSM-III (Spitzer, 1984) has encouraged many specialty groups to develop supplementary axes relevant to their own needs, and some of these may be of sufficient general importance to be considered for inclusion in future multiaxial systems. Given that clinicians do not have unlimited time to record all the information that might be coded as part of a psychiatric diagnosis, the role of supplementary axes in general, and Axes IV and V in particular, will probably be a more contentious issue in future than it was prior to DSM-III. In the process, psychosocial factors might be relegated to a level of secondary information which it is valuable to have, but not necessarily in a standard format for all cases. In the attempt to produce operational definitions which would be applicable to all patients and usable by any clinician, the creators of Axes IV and V may have been obliged to over-simplify the concepts. It may therefore be better to recognise the many difficulties that exist in assessing psychosocial factors (Rutter *et al*, 1975; Cleary, 1981; Paykel, 1983), and leave their assessment to individual clinicians, rather than diverting clinical and research effort into inadequate measures of important variables. On the other hand, it would be unwise to abandon the experiment with these Axes before their usefulness has fully been studied.

In the absence of simple and widely accepted measures of psychosocial stress and adaptive functioning, the recorded opinion of an experienced clinician is by no means a bad choice, provided it is not arbitrarily constrained by premature attempts at operationalisation. In practice, if Axes IV and V survive at all, it is likely to be in some such form, if only as a compromise between the information one would like to have, and what busy clinicians have time to assess and record. This paper attempts to answer some of the questions which arise within that context.

The first question is whether or not judges show reasonable agreement in their ratings on Axes IV and V for adolescents. The data on children and adolescents of the DSM-III field trials (Spitzer & Forman, 1979; Williams & Spitzer, 1980) suggest that this is not the case (intraclass reliability coefficients [ICRC] for Axes IV and V were respectively 0.59 and 0.52), but the methodological problems of those trials (Rutter & Shaffer, 1980) leave open the possibility that greater reliability might be obtained in other circumstances. Hence, the initial aim of this present work was to test the level of inter-rater agreement obtainable over a period of time between two judges with considerable prior experience of DSM-III, and using a standard set of recorded information. Unfortunately, the most similar study on the reliability of DSM-III in adolescents (Strober *et al*, 1981) used a draft which did not include these axes, and the case-history study of Russell *et al* (1979) also used a draft of DSM-III in which the psychosocial axes were not in their final form, so that their average figures of 63% agreement for 'Axis IV' (presence or absence of 28 stressors) and 64% agreement for 'Axis V' (a four-point scale of *present* impairment of adaptive functioning) have no direct bearing on these axes as they appear in the final version of DSM-III. Nevertheless, these findings agree in suggesting that assessment of psychosocial factors in young patients is not very reliable.

This raises an issue which is often passed over in reliability studies—the operational definition of 'reliability' itself. Even if there were no other differences between the DSM-III field trials and the study of Russell *et al* (1979), it would be impossible to compare them directly because they use different measures: intraclass correlations in the former, and percentage agreement in the latter. Mitchell (1979) showed that different definitions of reliability measure different *kinds* of reliability and we have therefore calculated a variety of measures for our data.

Another aim of the study was to explore beyond the confines of the present definitions of Axes IV and V, in the hope of finding ways in which such clinical ratings might be improved: the most direct way is to have an alternative measure. Since Axis IV has received most criticism, a modified version of the adversity index described by Shaffer *et al* (1975) was included for comparison.

Method

All adolescents referred to Rivendell Adolescent Unit for assessment from March 1983 to February 1984 were considered. A case was selected only if all of the following data were available: (1) information from the referring agency; (2) Rivendell Questionnaire, covering demographic, medical, developmental and school data (copy available on request); (3) Child Behavior Checklist for ages 4–16 (Achenbach & Edelbrock, 1979), completed by the parents; (4) Youth Self-Report for ages 11–18, completed by the adolescent (Achenbach & Edelbrock, 1983); (5) a 38-item questionnaire focusing on behaviours relevant to the assessment of attention-deficit disorders, completed by the parents (copy available on request); (6) Parental Bonding Instrument (Parker *et al*, 1979), completed by the adolescent; and (7) assessment report based on interview/s with the family and the adolescent by a psychiatrist or clinical psychologist and a social worker.

When information was complete—usually 2 or 3 weeks after initial assessment—the same two clinicians (J.M.R. and J.M.P.), with 3 years' prior experience in the use of DSM-III, made independent diagnoses on the five DSM-III axes and assigned a rating on the Psychosocial Adversity Index (PSAI). Once the independent DSM-III diagnoses were made, the cases in which there was disagreement on Axis I (clinical psychiatric diagnosis) were reviewed by the same two clinicians, and a diagnosis made by consensus. For the purposes of some analyses, these consensus diagnoses were grouped into three broad categories: (1) 'conduct', which includes conduct disorders, attention-deficit disorders and adjustment disorders with disturbance of conduct; (2) 'emotional', comprising affective disorders, adjustment disorders with depressed mood, anxiety disorders, and adjustment disorders with anxious mood; (3) 'other', including all other diagnoses. For similar reasons, cases in which one of the raters had participated in the assessment interview (seen) were distinguished from those where neither judge had been involved (not seen), there were no cases in which both raters had interviewed the family. Diagnoses on Axis II (personality disorders and specific developmental disorders) and Axis III (physical disorders) are not considered here.

The rating of severity of psychosocial stressors (Axis IV) was made according to the procedures in the DSM-III manual. The key features of that rating (on a seven-point scale from 1 (no apparent stressor) to 7 (catastrophic) are that judgement should be based on the hypothetical stress which an 'average' adolescent in similar circumstances and with similar sociocultural values would experience from the particular psychosocial stressor(s); that stressors occurring in the 12 months prior to the onset of the current disorder should be considered; and that ratings "should reflect the summed influence of all the psychosocial stressors". These requirements are difficult to apply, but no attempt was made to define them further, since our aim was to use DSM-III as it stands.

Ratings on Axis V are supposed to reflect the highest level of adaptive functioning during the previous year, taking into consideration the patient's performance at work (or school), at home and in the use of leisure time. Ratings may range from 1 (superior) to 7 (grossly impaired).

The PSAI attempts to measure the more chronic, enduring stressors or 'adversity'. This instrument is a simplified version of a scale developed by Shaffer *et al* (1975), in which patients are given one point for each of the following items: (a) broken home or chronic marital disharmony, (b) contact with two or more social agencies, (c) psychiatric disorder or chronic physical illness in mother, (d) psychiatric disorder or chronic physical illness in father, (e) four or more siblings; and the number of points is summed to obtain a rating of adversity between 0 and 5.

For all three measures, five indices of inter-rater agreement were calculated: ICC(2,1) and ICC(3,1) are related intra-class correlations calculated according to the procedures in Shrout & Fleiss (1979). ICC(2,1) differs from ICC(3,1) in including the variance associated with additive biases of judges as part of the error variance, and is usually lower. The other correlational measure calculated is the ordinary product moment correlation (PMC).

These measures share a common problem: they are not robust because they can be affected drastically by outliers—a few large discrepancies or agreements at extreme points of the range (Mosteller & Tukey, 1977). To compensate for this deficiency, two other measures of agreement were calculated: percentage exact agreement (PEA) and percentage close agreement (PCA). PEA is the proportion of cases, expressed as a percentage, in which both judges gave the same numerical ratings; PCA is similar, but includes the cases in which raters differed by a single scale point. PEA and PCA have many disadvantages (Bartko & Carpenter, 1976), but the robustness arising out of the fact that they simply count agreements and disagreements, irrespective of their magnitude, is useful (Paykel, 1983). Together, these measures are complementary. Where they agree, it is probable that all is well with the data; where they disagree, the pattern may give an indication as to the nature of the problem. For example, ICC(2,1) is sensitive to both additive and multiplicative biases of the raters; ICC(3,1) is sensitive to multiplicative biases only; and PMC is sensitive to neither, so that the relative values of these indices may be used to assess rater bias. Similarly, if all correlational measures are low, while PEA and PCA are fairly high, it is likely that there are outliers, or that there is a restriction of range in the ratings.

Apart from this statistical exploration of sources of unreliability, the reliability within various subsets of the data was also calculated to see if procedural or patient variables altered the reliability.

Results

The 140 adolescents who were included in the study represented 67% of all assessments during a period of 10 months. The only reason for exclusion of a case was incomplete data at the time the sample for this report was finalised: most of the omissions were because a particular nurse-administered questionnaire was not completed, due to the nurse concerned having been unavailable. With few exceptions, the remaining omissions resulted from the arbitrary reporting date in an ongoing study, which meant that the coverage during the early part of the period was complete, while in the latter part, more cases were not included because routine clerical tasks (typing of assessment reports, collection of case files etc.) had not been done. Though it is unlikely that this sampling procedure would be biased toward 'easy' cases, if there was any such bias, it should become apparent as a difference in reliability between the first and second half of the sample.

TABLE I
Inter-rater reliability for DSM-III Axis IV, Axis V and PSAI for the sample of 140 adolescents and two judges

Measure		*Axis IV*	*Axis V*	*PSAI*
ICC(2,1):	Estimate	0.44	0.58	0.68
	95% CI	(0.27–0.58)	(0.45–0.69)	(0.57–0.76)
ICC(3,1):	Estimate	0.46	0.58	0.68
	95% CI	(0.31–0.59)	(0.45–0.69)	(0.57–0.76)
PMC		0.50	0.58	0.68
PEA		41%	45%	54%
PCA		82%	89%	89%

The results for the total sample, all measures and all indices of agreement are given in Table I. The three correlational measures are identical for Axis V (0.58) and for PSAI (0.68); while the differences for Axis IV are small and negligible in relation to the sampling variability of the estimates as indexed by the associated 95% confidence intervals (95% CI). The percentage agreement figures provide a convenient interpretation of the variability of the ratings: for example, when rating Axis IV, the judges agreed exactly in 41% of the cases, disagreed by one scale-point on a further 41%, and by two or more scale-points on the remaining 18% of cases.

On all indices of agreement, Axis IV was rated less reliably than was Axis V or PSAI, while Axis V ratings were less reliable than PSAI on all indices except PCA, which was equal for both; the 95% CI for ICC(2,1) and ICC(3,1) lend statistical support to these differences. There was practically no overlap in the ranges for Axis IV and PSAI; while the point estimates of 0.58 for Axis V lay at the top of the 95% CIs surrounding the Axis IV estimates, and at the bottom of the 95% CIs surrounding the PSAI estimates.

The remaining results are based on subdivisions of the total sample according to two methodological variables—experience/practice (first 70 cases *vs* last 70 cases) and source of interview data (seen/not seen)—and according to three patient variables—age (12–13 *vs* 14+), sex and diagnostic group (conduct/emotional/other).

Since the sample is not large enough to support simultaneous application of all these dimensions, the procedure adopted for the exploratory analyses was to calculate point-estimates of ICC(2,1) separately for the data in any subdivision, and treat as chance variation any estimate lying within the 95% CI for the same variable in the overall analysis (Table I). This is an arbitrary decision rule, since the probability of type I and type II errors is indeterminate, but it serves the practical purpose of calling

TABLE II

Inter-rater reliability for two judges rating Axis IV, Axis V and PSAI for a sample of 140 adolescents subdivided by position in case sequence and type of interview data

	Seen	*Not seen*	*Total*
Number of cases			
First 70 cases	32	38	70
Last 70 cases	31	39	70
Total	63	77	140
Axis IV, ICC(2,1)			
First 70 cases	0.48	0.41	0.45
Last 70 cases	0.37	0.46	0.43
Total	0.43	0.43	0.44
(95% CI)			(0.27–0.58)
Axis V, ICC(2,1)			
First 70 cases	0.58	0.54	0.57
Last 70 cases	0.54	0.60	0.58
Total	0.58	0.56	0.58
(95% CI)			(0.45–0.69)
PSAI, ICC(2,1)			
First 70 cases	0.68	0.47	0.55
Last 70 cases	0.79	0.78	0.79
Total	0.73	0.64	0.68
(95% CI)			(0.57–0.76)

attention only to large differences. A problem of this approach is the possible restriction of range of the variables in question (Axis IV, Axis V and PSAI) within the relatively homogeneous subgroups produced by subdividing the sample on patient variables such as age, sex or, particularly, diagnosis. If patients genuinely do not vary or if, for whatever reason, the judges assign similar ratings to patients within such a subgroup, to report an intraclass correlation would be misleading. Following Lahey *et al* (1983), the between-patient variation within each subsample was first tested to see if there was a statistically reliable main effect for patients. For samples which failed this test, the ratings are described as 'unreliable'.

Table II shows the results of the analysis of the first half of the sample *vs* the second, and for the patients seen and not seen. For Axes IV and V, there is no suggestion that either of these variables alone or in combination have any effect on reliability. For PSAI, however, the picture is somewhat different—this was rated more reliably for the last 70 cases in the study. There is also the indication of an interaction, since the lower reliability for the first 70 cases is particularly marked for the 38 cases who were not interviewed by either rater. Unless it is assumed that PSAI was affected by sample selection when ratings for Axes IV and V were not, this suggests that the sample was representative of the referral population.

There were 18 girls in the group of 12–13-year-olds and 29 in the 14+-year-olds; the figures for boys were respectively 51 and 42. Although girls made up 34% of the total sample, they seem to be under-represented in the younger age group (26%), and over-represented in the older age group (41%); this difference just failed to be statistically significant, but is still important. The most unusual result of this analysis is the unreliability of Axis IV ratings for girls, which occurred largely because of a lack of variation in ratings, so that the patient effect for girls overall and in each age group was not statistically reliable. Reliability of Axis IV ratings for younger (0.48) and older boys (0.52) and for boys overall (0.50) were well within the range of sampling variation (0.27–0.58), as were the ratings for younger (0.49) and older patients overall (0.40). For Axis V, reliability was much the same for younger (0.63) and older boys (0.59), and younger (0.56) and older patients (0.57), but reliability for younger girls (0.36) was lower than that for older girls (0.51), and was also the only result to lie outside the 95% CI for Axis V (0.45–0.69). For PSAI, there is no indication that reliability is different for boys (0.67) and for girls (0.69) respectively, but reliability seems to be higher for younger patients (0.74 *vs* 0.63), though both values are within the 95% CI (0.57–0.76).

There were 17 girls in the 'conduct', 16 in the 'emotional' and 14 in the 'other' groups; the numbers for boys were 45, 23 and 25 respectively. As might have been expected from the previous results, Axis IV ratings were also unreliable for girls in each diagnostic group. The corresponding results for boys (conduct: 0.47; emotional: 0.56; other: 0.52) are well within the 95% CI (0.27–0.58), and so too are the overall results for each diagnostic group (0.44, 0.51 and 0.37 respectively); Axis V ratings for girls in each diagnostic group were also unreliable. With the exception of boys in the 'conduct' group (0.35) and that group as a whole (0.39), the remaining results lie within the 95% CI for this axis (0.45–0.69). For PSAI, sex differences were small within each diagnostic group (conduct: 0.62; emotional: 0.56; other: 0.83), and only one of the overall results falls inside the 95% CI (0.57–0.76).

Discussion

Comparison of the present results with those of the DSM-III field trials (Spitzer & Forman, 1979; Williams & Spitzer, 1980) is complicated by procedural differences and by some uncertainty about the reliability index used in those trials. The statistic used in them is probably comparable with ICC(2,1); it was described both as 'the kappa coefficient of reliability' and as 'the intraclass reliability coefficient' (ICRC) in the DSM-III manual and by Spitzer & Forman (1979). The statistic that best fits that double label is the 'weighted kappa' described by Fleiss & Cohen (1973), which, for moderately large samples and two judges, is essentially the same as ICC(2,1) in its calculation. For the overall sample in the present study, weighted kappa took the same numerical values as those for ICC(2,1) given in Table I. In what follows, therefore, it will be assumed that ICRC and ICC(2,1) have similar interpretations.

Within the field trial data themselves, there are some puzzling results, which require explanation before proceeding to comparisons with the present data; the main one is the difference in reliability between adult and child/adolescent patients. Reliability for the Phase II draft of the DSM-III was better for adults than for children/adolescents (Axis IV: 0.66 *vs* 0.59; Axis V; 0.80 *vs* 0.52); whereas reliability for the earlier Phase I draft was worse for adult than for younger patients (Axis IV: 0.58 *vs* 0.75; Axis V: 0.75 *vs* 0.77) (Williams & Spitzer, 1980). At face value, this suggests that the changes made to the definitions of Axes IV and V improved reliability for adults and substantially reduced reliability for children/adolescents. The result cannot reasonably be explained by a change in procedure between the Phase I and Phase II trials—the reduced proportion of jointly *vs* separately conducted interviews—since the change from a 60:40 ratio for Phase I to a 33:67 ratio in Phase II would have been expected to affect reliability for adult and younger patients in the same way; in any case, the differential reliability achieved with joint interview *vs* separate interview (Axis IV: 0.62 *vs* 0.58; Axis V: 0.80 *vs* 0.69) (Spitzer & Forman, 1979) is not large enough to explain the decline of reliability in younger patients. Nor can the results readily be explained by practice effects. It can be inferred by comparing Spitzer & Forman (1979) with Williams & Spitzer (1980) that most of the judges who contributed Phase II ratings for adults had previously contributed Phase I ratings, and since only some 15 'practice' cases were required before contributing ratings, it is possible that at least some of the improved reliability of the Phase II ratings might be due to increased familiarity with the general procedure (as found in the present data for PSAI). On the other hand, it seems that only about half the child/adolescent Phase II judges had previously contributed Phase I ratings, so that a smaller improvement might have been expected. The actual result of a substantial decline in reliability for younger patients is not consistent with this pattern.

In the absence of evidence on the statistical reliability of the ICRC estimates provided by Spitzer & Forman (1979) and Williams & Spitzer (1980), it is not worth while to pursue these differences further, but these analyses suggest that it is not possible to use the DSM-III field trial data to predict the reliability that might be expected in the present study. It would be simplistic to suppose that reliability for adolescents ought to lie somewhere between the adult and the child/adolescent figures, since there is no *a priori* reason for supposing that reliability increases with the age of the patient: it is quite possible that the lower reliability for a mixed adolescent/child sample was because of poor reliability for adolescents rather than children. As in the present data, reliability for different subgroups may be quite different, and overall reliability for a heterogeneous group provides no indication of specific effects of this kind. Against this background, the overall results obtained in the present study (Table I) and the detailed results for various subgroups (Table II) are best interpreted as independent evidence of the relatively poor reliability of Axes IV and V in adolescent patients.

There are other aspects of both protocols which also limit generalisation of their results. Reliability is more than just consistency: it is consistency achieved in the face of diversity. The more diverse the sample of patients and judges, the more variable the information input, the longer the span of time covered by the study (or, in brief, the more the study reflects the diversity of the real world), the more likely it is that the results obtained can be generalised safely to other patients, judges, records and times. Neither the DSM-III field trials nor the present study are adequate in that sense. The basic unit in all the DSM-III data is a tetrad of two colleagues from the same institution—and probably with similar biases—rating two nearly successive patients, after each has interviewed them and read all other relevant information. For comparison, the basic unit in our study might be said to be similar: two colleagues, two patients, but in some cases working from case file data, and in some cases with one of the clinicians having conducted the interview. Within that basic unit, therefore, one might have expected somewhat better reliability in the DSM-III data. However, there is considerable difference in the way that both studies extended this over the patient–rater universe. The field trials did so by drawing, more or less at random, another tetrad of two patients and two raters, while we did so by using the same raters for new patients.

At first glance, it might seem that the DSM-III data would thus be more general; it does, after all, sample many more rater pairs with the same (adolescent/child) number of patients. Though this is true, it is important to note that, no matter how many such samples are drawn, each rater only makes decisions about two patients (or in some cases four), judged within a short time-span. There is no scope for long-term variation in performance across many patients to have its effect, and, in fact, there is good reason to suppose that ratings of only two consecutive patients would tend to be comparative judgements (which would increase concordance of rank ordering), rather than judgements referred independently to a common yardstick. Anyone who has marked examination papers is familiar with this phenomenon. Conversely, the reliability figure for the present study does include long-run variation in performance over a period of 10 months. As far as patients are concerned, there is no good reason to suppose that either sample would be inadequate, but by sampling many patient/rater/institution combinations, the DSM-III trials gave better coverage of 'between institution/between colleagues' variation than our study did. Thus, the point of this analysis is to suggest that the data available from the field trials and the present study should be seen as indicating the reliability achievable under different kinds of restriction of diversity, and the results are not encouraging.

An unexpected finding of the present study is the very low reliability of the ratings in Axes IV and V for adolescent girls, which occurred because of a lack of variation in ratings. As noted by Lahey *et al* (1983), this may occur because the patients are truly similar or just because the judges consider them to be so. Since there is no reason to suppose that adolescent girls are very similar in their levels of psychosocial stress, an alternative explanation may be that male judges have difficulties in assessing the severity of psychosocial stress, as defined by DSM-III, for adolescent girls.

However, the most useful data are those for PSAI; not only is it the most reliable measure on all indices (Table I), but it is also the most constant throughout the various subdivisions except one. PSAI reliability was lower in the first half of the data and seemed to depend on the source of interview data, whereas, in the last 70 cases, reliability was higher and the same irrespective of who conducted the interview. The first result suggests that experience with even an 'objective' measure of this kind is necessary. The second is no surprise: PSAI relies on objective data for the most part and has an explicit rule for its summation, rather than the requirement that the rating should reflect (in some unspecified manner) 'the summed influence' of stressors.

The results of this work have some broad implications for other reliability studies in this area. There is little evidence that interview by the rater makes an important contribution to reliability if an adequate set of questionnaire data is available and an interview has been conducted and reported. On the other hand, there is some suggestion that the sex of the patient and the sex of the rater may be important; that reliability may improve with experience of a new measure (PSAI); that it is important to look at long-run reliability; and that partitioning the data and using multiple measures can give useful insights. Exploratory analyses of this kind provide only 'indications' (Tukey, 1977; Mosteller & Tukey, 1977) of effects, and do not have the same status as formal statistical inferences, but such indications can be useful. For example, any measure which is intended for general clinical use should be immune to minor variations of the protocol and irrelevant patient variables such as age and sex. The indications that Axis IV ratings were not 'robust' in this sense should be considered when planning alternative measures. Finally, some of the data suggest that the main source of unreliability is likely to be the operational definitions of Axes IV and V.

Life Events and Mania
A Special Relationship?

A. AMBELAS

Fifty patients in their first manic episode were compared retrospectively with groups of (a) manic patients in other than first admissions and (b) acute surgical cases. They were then followed up for 3–8 years. First manic admissions were linked to life events far more frequently – 66% *vs* 20% and 8% respectively for the other groups. Within-group comparisons showed patients with life events were much younger. The link between life events and manic episodes appeared immediate and selective, a view further supported by the findings of the follow-up. Later episodes precipitated by life events seem to require smaller amounts of stress. The possible role of life events in relation to mania is discussed.

Anecdotal reports linking manic episodes to major life events have appeared over many years in the psychiatric literature of many countries and in many languages (Bonnafous-Serieux & Ey, 1938; Stern, 1944; Parkes, 1964; Borgna, 1964; Scotti & Cerletti-Scotti, 1969; Hedri, 1976; Rickarby, 1977; Hollender & Goldin, 1978). Attempts to quantify this association have been much more scarce. Of those few that exist, the earlier ones (Blankenburg, 1964; Tölle & Fritz, 1971) were plagued by methodological weaknesses. The recent surge of interest in life events has tended to neglect mania. Few papers have focused on the condition specifically. Dunner *et al* (1979) looked at life events in the context of researching bipolar affective illness. Two-thirds of their patients with a manic first episode reported preceding life events, and among these a great preponderance were male. Ambelas (1979) compared patients with manic episodes with a control group of acute surgical admissions and found life events preceding the manic episodes in 28% of his sample, five times more frequently than in the control group. Kennedy *et al* (1983) used manic patients as their own controls and observed a far higher frequency of life events in a period prior to the manic episode than during an equal subsequent period of time. Lastly, Glassner & Haldipur (1983) found life events common in late onset bipolar patients, but not in early onset ones, where the cut-off point for early onset was at 20 years of age!

In recent years, a number of papers have appeared on other forms of causable mania; Krauthammer & Klerman (1978) introduced 'secondary' mania, a variety where somatic illness or a chemical substance is implicated as a cause. 'Post-partum' mania appears to be recognised and diagnosed far more frequently than had been the case earlier (Brockington *et al*, 1978; Kadrmas *et al*, 1979; Dean & Kendell, 1981; Katona, 1983).

Aims of the study

(a) To add to the still meagre body of information on the subject.
(b) To confirm or refute observations suggestive of a greater frequency of life events prior to first manic episodes than prior to subsequent admissions.
(c) To identify differences between patients whose episodes were related to life events and those whose episodes were not preceded by life events.
(d) To examine the evidence contained in the data with reference to 'post-partum' mania and to 'secondary' mania.
(e) To look at patterns of further morbidity, while maintaining the focus on life events.
(f) Finally, to attempt to promote the understanding of the role of life events in the precipitation or causation of manic episodes.

Parts of the study

There are two distinct but inter-related parts in this work.

The incidence study

We identified and studied patients in their first manic episode. The purpose of this was to examine the connection between life events and the manic presentation of affective illness and not with manic-depressive illness as a whole. Therefore, patients who had earlier depressive presentations, but not manic ones, were included in the study.

The follow-up study

We examined the course of the illness of the patients in the incidence study over a period of 3–8 years, with a specific interest in further life events.

The incidence study

Method

Patients

The patients were identified from the health authority's records of discharges. During the period 1974–1981, 340 patients were admitted to Walsgrave Hospital, Coventry, with a diagnosis of mania. Their case notes were screened and 50 were found to have had their first manic episode during that period. This figure matched the expected incidence over 8 years for a catchment area of 500 000. The sample consisted of 24 males and 26 females with an age range of 16–76 and a mean age of 34.8 years. All patients had received mainstream education and none had attended a special school. Thirty-six were currently or had been married and 14 were single, mainly the younger ones.

Controls

Two control groups were used for comparisons:

(a) A group of 40 patients who had been admitted for manic episodes other than their first. They were extracted from the data of an earlier study by the present author, after the exclusion of those in the original sample who were then presenting with their first manic episode. This group did not differ from the index group in terms of sex distribution, but it did differ in terms of age with the mean age 46.3 years.

(b) Because there is evidence that life events tend to be reported more frequently by younger patients, it was necessary to have an age-matched control group. A group of acute surgical cases was used, matched for sex, age and education; although not matched individually in terms of marital status, these patients as a group did not differ significantly from the patients in terms of this parameter.

Diagnosis

A diagnosis of mania had on all occasions been made by the consultant psychiatrist responsible for the patient's care (the investigator did not have the clinical responsibility for any of those patients). The diagnoses were verified against the research criteria of Feighner *et al* (1972).

TABLE I
Mean scaling scores for 49 events

Rank in English sample	*Event*	*Mean*
1	Death of child	19.53
2	Death of husband/wife	19.14
3	Being sent to gaol	17.76
4	Death of close family member	17.65
5	Serious financial difficulties	17.58
6	Miscarriage or stillbirth	16.96
7	Court appearance for serious offence	16.94
8	Business failure	16.68
9	Marital separation due to arguments	16.57
10	Unwanted pregnancy	16.48
11	Divorced	16.29
12	Fired	15.93
13	Death of close friend	15.70
14	Serious illness of family member	15.52
15	Unemployed for 1 month	15.43
16	Serious personal physical illness	14.67
17	Involved in a lawsuit	14.47
18	Fail important exam or course	14.38
19	Losing or being robbed of personally valuable object	14.34
20	Demotion	14.33
21	Taking a large loan (more than half annual salary)	13.64
22	Break engagement	13.12
23	Child marries without approval	12.69
24	Separation from significant person (e.g. close friend)	12.01
25	Prepare for important exam	11.41
26	Marital separation not due to arguments	11.33
27	Move to another country	11.14
28	Son enlists or drafted in forces	10.82
29	New person moves into home (e.g. relative, lodger)	10.13
30	Retirement	10.05
31	Change in work hours or conditions (overtime, second job, new boss, reorganisation)	9.68
32	Cease going out with steady boyfriend/girlfriend (after at least 3 months)	9.36
33	Change in line of work	9.24
34	Move to another city	8.57
35	Marital reconciliation	7.96
36	Child leaves home (e.g. college)	7.85
37	Wife becomes pregnant	7.08
38	Birth of child (for mother)	7.03
39	Change school, college or university	6.79
40	Birth or adoption of child (for father)	6.49
41	Begin full- or part-time education	5.91
42	Promotion	5.89
43	Move within same city	5.50
44	Marriage	5.44
45	Finish full-time education	5.26
46	Become engaged	4.25
47	Child engaged	3.72
48	Wanted pregnancy	3.70
49	Child marries (with approval)	3.14

Events and interviews

The presence or absence of life events was recorded by the medical officers responsible. The events needed to comply to the principles described by Brown & Birley (1968). Furthermore, they had to be contained in a checklist of events derived from that used by Paykel *et al* (1976), shortened by the omission of such events that were most subjective in quality (Table I). For the purpose of quantification, events were given the scaled scores arrived at by Paykel *et al.*

Events were required to be independent of the illness and to have occurred prior to the onset of the manic episode. Judgement on their independence and timing was based on evidence given by an independent witness, usually a close relative. Fortunately, on all occasions such an interview was present on record. Particular attention was paid to events which could well be dependent, e.g. separations, engagement. On those occasions, the patients themselves were interviewed, inevitably at a later date, by the investigator. When doubts remained, patients were removed to the group negative for life events. The period between an event and the patient's admission was kept to 4 weeks. Dates of admission were used in preference to dates of onset, because they are harder data and because the delay between apparent onset and admission was usually very brief. The case notes of the surgical controls could not be expected to contain relevant information; the patients were interviewed by the researcher on the basis of the seven types of events suggested by Brown & Birley (1968), facilitated by the above checklist and always within 10 days from their admission.

Weaknesses of the method

(1) The use of case notes and the reliance on recording by the clinicians responsible introduced the likelihood of sporadic and biased recording. On the other hand, it also excluded investigator bias and the 'invitation to report'.

(2) The use of a shortened version of Paykel *et al* (1976) event list could result in some positive cases being excluded.

(3) Limiting the admission period to 4 weeks could also reduce further the number of positive cases.

Still, these flaws were more likely to result in false negatives rather than false positives.

Results

Comparisons with control groups

Of the 50 patients who had suffered their first manic episode during the period the study covered, 33 (66%) were found to have experienced life events preceding their admission. Even this high figure of positive cases is likely to be an underestimate resulting from the design of the research.

Among the 50 surgical controls, only four (8%) reported an event during the 4 weeks prior to admission. The difference between the groups is striking.

A group of 40 manic patients in a repeat admission included eight (20%) positive for recent life events: (manic first episodes *vs* controls: $\chi^2 = 33.6$, $P < 0.001$; manic first episodes *vs* manic repeat admissions: $\chi^2 = 17.4$, $P < 0.001$). We concluded that life events are more closely linked with first manic episodes than with repeat manic episodes and more so than with acute surgical treatment.

Comparisons between positive and negative groups

Sex. Among patients positive for life events, the ratio of males to females was 16:17. Among negative patients, the sexes were also equally represented. The study failed to confirm the observation by Dunner *et al* (1979) who found manic episodes preceded by life events more frequently in male patients.

Age. The mean age of patients positive for life events was 28 years. The mean age of negative patients was 48.1 years. Figure 1 presents the age distribution for the positive and negative groups. It can be seen that there is difference both in the position and the shape of the curves.

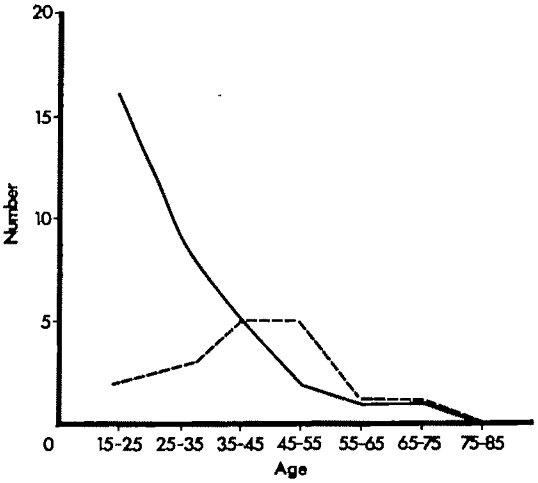

FIG. 1 Age at onset of first manic episode of patients positive (——) and negative (– – –) for life events.

Clinical picture. The groups were compared in terms of the frequency of the common symptoms of mania. No significant differences between positive and negative patients were found. However, there was a slight tendency for positive patients to present more paranoid features.

Previous depressive episodes. Because the first *manic* episode rather than the first manifestation of psychiatric illness was the basis for inclusion of patients to the study, some were expected to, and indeed did, have earlier episodes of depression. Among the 33 positive patients, six (18%) had such an episode, while among the 17 negative ones, nine (53%) had earlier depressive episodes. The difference is statistically significant ($\chi^2 = 4.90$, d.f. = 1, $P < 0.05$; Yates' Correction). This finding raised the question of whether the age differences between the groups were due to this factor alone. Exclusion of patients with earlier depressive episodes brought the mean age for positive patients down to 26.4 and for negative patients down to 43.5 years. Thus, the presence of previous depressive episodes could not account for the age difference.

Family history. Information about the family history, which was recorded in the notes, tended to be somewhat vague, especially with regard to the accuracy of diagnosis. We defined a positive family history as 'any mention of psychiatric problems in first and second degree relatives'. Evidence of positive psychiatric family history was found in eight (25%) of the positive and five (29%) of the negative patients. A definite diagnosis of mania in a first degree relative was found in only two positive and two negative patients. Thus, in the group positive for life events there was no evidence of familial loading which could account for their younger age as a result of greater genetic vulnerability.

Recovery after a depressive phase. Over half the positive and negative patients reached a stabilisation of their mood after a period of depression. The occurrence of a period of depression in such a high proportion of all manic patients may be an important observation.

The life events. Table II presents the life events which preceded the manic episodes in the positive cases. 'Deaths' included deaths of relatives and friends; 'separations' included divorces, breaks of engagement and terminations of steady relationships. The one case described as 'other' represents a combination of three different events from the list which all took place within the 4-week period under consideration.

Table III shows the frequency of occurrence of life events characterised as pleasant or unpleasant and entries or exits. It was considered inappropriate to characterise the birth of a child as either pleasant or unpleasant, since emotional uncertainty is very often present. This uncertainty is clearly shown by the fact that all childbirth-related events (wife pregnant, birth of child for mother, birth or adoption of child for father) in Paykel *et al*'s list showed some of the largest standard deviations from the mean scaling scores. Table III shows also that pleasant events were very rare before manic episodes. Only an engagement qualified for this group.

The four events among the surgical controls did not include any deaths or births. There was one separation and the other three were all related to employment.

TABLE II
Form of life events

	Event	*No.*	*%*
1	Deaths	8	24.24
2	Birth of child (for mother)	7	21.21
3	Birth of child (for father)	3	9.09
4	Personal health problems	3	9.09
5	Separations	5	15.15
6	Exams	3	9.09
7	Work related problems	2	6.06
8	Engagement	1	3.03
9	Other	1	3.03
	Total:	33	100%

TABLE III
Character of life events

	Events and stresses	*No.*	*%*	*Comments*
1	Pleasant	1	3.03	Births not included
2	Unpleasant	22	66.6	
3	Entries	10	30.30	
4	Exits	13	42.39	

In none of the subgroupings does the percentage total 100% since there are always events that cannot be classified.

Timing of events. Figure 2 shows the time delay between event and admission. The 4-week limit did not lead to the exclusion of any great number of cases. There were only two cases excluded on this basis—a birth 30 days before admission and a death 40 days before. The time relationship between events and manic admissions appeared close. An earlier finding of a delay in admission when the event was a bereavement (Ambelas, 1979) was not confirmed.

Mania and physical illness. In seven cases, there was a definite connection with poor physical health. On three occasions, the circumstances could be construed as definite events—two hysterectomies and one emergency admission for ruptured emphysema. In all three cases, these events occurred less than 10 days prior to the onset of mania. The other four patients had well established chronic illness (Stein-Leventhal syndrome, Addison's syndrome, hyper- and hypothyroidism) and were receiving active treatment. Thus, all four illnesses had a hormonal aspect. A positive family history of affective illness was not found in any of these cases.

'Post-partum' mania. The present study identified seven first manic episodes presenting in the puerperium. The onset was related closely in time to the birth, but this was the

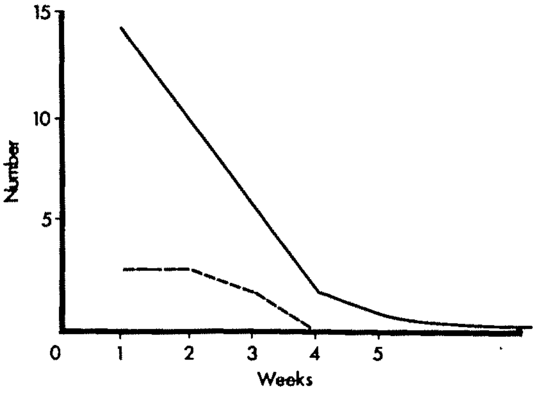

FIG. 2 Timing of life event prior to admission (——, all events; ——, event death).

case with all life events and the manic episodes they precipitated. The sample included three 'new fathers'.

The follow-up study

Method

The patients were followed for 3–8 years. The scope of this follow-up was limited and the focus was maintained exclusively on the occurrence of life events prior to further affective episodes. An early paper on reactive mania (Stern, 1944) suggested that, once a manic mechanism had been set up, further episodes could be precipitated by less severe events. Eventually a point might be reached when no event could be elicited. An attempt was made to look for evidence which would support this view.

Even though it would now have been possible to give the follow-up a prospective character, it was decided not to follow such a course, because it would destroy the comparability between first and other than first episodes. It was again left to the consultants responsible to diagnose, record events and interview relatives. The relevant data were then extracted from the case material. The same restrictions were applied and patients were interviewed only at a later date.

Results

The original cohort of 50 patients had a total of 59 readmissions. Of these, 43 were admissions of the 33 patients originally positive for life events and 16 were readmissions of the 17 negative ones. The difference in overall morbidity was not significant.

Among patients originally negative for life events, further admissions were predominantly manic (12/16). Of the 43 readmissions of positive patients, 29 were due to manic and 14 to depressive episodes.

Events were found prior to 20 readmissions, of which 18 were manic and only two depressive, while among the 23 admissions not precipitated by events, 11 were manic and 12 depressive. These differences are statistically significant ($\chi^2=8.67$, $P<0.01$). It is concluded that life events are perhaps selectively related to manic episodes.

Stress severity

In order to test the hypothesis that less severe stress precipitates further admissions, some means of quantification was needed. The scaled scores for life events determined by Paykel *et al* (1976) for English subjects were available (Table I). While there were large standard deviations for many events, suggesting significant differences in individual appreciation of stressfulness for a particular event, the alternative of getting individual scores from our patients was not chosen, because it was thought that patients would be likely to over-score events they had recently experienced.

From the list, each recorded event was allocated the mean scaling score corresponding to it. Scores for events related to first admissions and for those related to readmissions were averaged. The resulting means were 12.08 for events related to a first episode and 8.01 for events before readmissions. There was a clear difference and the finding supported the hypothesis that repeated manic episodes require less stress for their production.

Discussion

Two-thirds of patients admitted to hospital with their first manic episode reported life events that had preceded the onset of their illness. This association with life events was significantly higher than in subsequent admissions with mania, where life events were found in one-fifth of patients, and even more so than in the month before admission of acute surgical cases where less than one in ten had experienced life events. The different frequency of events before admission due to a first manic episode or as a surgical case appeared valid. The tendency of precipitating events to be less severe before further admissions may have led to underestimation of the association with later admission, as their severity falls below a recording threshold and their independence becomes more doubtful.

The age difference between patients who experienced preceding events and those who did not was a surprising finding. It could not be explained by genetic differences, or by a greater number of earlier depressive episodes in the group without events. The tendency of younger subjects to report more events must also be discarded as a sufficient explanation, since it clearly did not lead to the age-matched surgical controls reporting many events. We are left with the observation that younger subjects are more likely to have event-related mania and a possible speculation that life events may be bringing the manic presentation forward in time—by as much as 20 years.

Four cases were found where a diagnosis of secondary mania could be applied. A hormonal factor was implicated in each case. Interestingly, in Krauthammer & Klerman's (1978) original series, steroids were the agents most commonly thought responsible. It may well be that a relevant association exists and this should be sought at the interface of psychiatry and endocrinology.

In recent years, there has been an increasing recognition of manic disorder during the puerperium, with Dean & Kendell (1981) finding 12.7% of all the admissions in the 90 days following delivery to be manic, while in Katona's (1983) sample the proportion rose to 22%. Both studies point out a tendency for the mania to appear very soon after the delivery. In more than one-fifth of our positive cases, the birth of a child was the life event and the onset of mania was immediate. This high proportion of births among the life events recorded would support the view of Kadrmas *et al* (1979) that childbirth may be a very 'special' event in the context of mania.

While the 'puerperal' notion has tended to imply biochemical causes, and related evidence exists, attention must be drawn to the presence of three 'new fathers' among the positive cases in the present sample where a biological link cannot be postulated.

Whether the role of life events is causal or precipitant can never be answered in an absolute manner. The findings of this study suggest that life events may have a specific and major responsibility for the manic presentation of affective psychosis. The observed temporal closeness between event and episode (also noted in puerperal illness), the selective association between life events and mania rather than depression in further episodes, would support such a view. Whatever the overall cause of manic-depressive psychosis, life events could be important for the manic component. This view does not contradict the evidence from genetic studies of the unipolar *vs* bipolar illness continuities. There is no reason why a specific diathesis and a life event could not both be required for the clinical picture of mania to be produced. Alternatively, the inherited diathesis may express itself as vulnerability to life events.

In a different vein, the psychodynamic model of mania (Klein, 1948) postulates a defence which is brought into play to protect the patient from the most destructive effects of depression and gives time for the slower mechanisms of reparation to take effect. This understanding requires a quick manic response to situations of loss, real or perceived. The findings of this study are consistent with such a model. The stress, very often loss, seems to be responded to by mania. The response is very quick, again as the theory assumed. Thus, a large number of patients go into a depressive phase before normalisation can be achieved, and mania could be construed as a temporary shield or buffer which makes the ensuing depression tolerable, or even causes it to be aborted.

Finally, the findings do not contradict the conceptualisation of mania as a syndrome of non-specific aetiology which can be brought into play by a variety of noxious stimuli—biochemical, hormonal but also, and quite frequently so, psychologically traumatic.

Acknowledgements

This study was supported by a grant from the West Midlands Regional Research Committee. I would like to thank my consultant colleagues who allowed me access to their cases, and Mr Peter Harvey, Lecturer in Clinical Psychology in the Department of Psychiatry at the University of Birmingham, and Mr K. W. Johnson, Regional Statistician at the West Midlands RHA for their technical assistance. Thanks are also due to Mrs Halina Johnson for the patience displayed in the preparation of the typed version.

Hysterical Personality Disorder

The Process of Diagnosis in Clinical and Experimental Settings

D. J. THOMPSON and D. GOLDBERG

A study of the case notes of 52 patients with a diagnosis of hysterical personality disorder showed that 27 had no recorded features of that condition, but were frequently described as aggressive, uncooperative, or attention-seeking. Although 60% were recorded as depressed, only 17% received antidepressant treatment. In an experimental study, the core traits of the disorder were found to have a low inter-rater reliability. Two patients, who had received hospital diagnoses of hysterical personality disorder, were shown to display behaviour that caused psychiatrists to make a diagnosis on wholly inadequate information.

The present classification of personality disorders remains unsatisfactory and attracts much criticism, particularly for the category of hysterical personality disorder (Presley & Walton, 1973). The status of this disorder as a diagnosis is closely linked with the clarity of the definitions: "It has been used to describe quite different and poorly delimited varieties of behaviour; 'hysterical' has taken on some of the attributes of both a fossil and a chameleon, so that it is understandable that there is a total failure of agreement as to just what is meant when something is referred to as 'hysteria' or 'hysterical'" (Chodoff & Lyons, 1958). The definition found in the ICD 9 provides a standard description: "Shallow, labile affectivity, dependence on others, craving for appreciation and attention, suggestibility and theatricality. There is often sexual immaturity, e.g., fridgidity and overresponsiveness to stimuli. Under stress hysterical symptoms (neurosis) may develop".

Perhaps the most successful attempt to refine the diagnosis is in DSM-III, where it has been renamed 'histrionic personality disorder' to avoid the semantic confusion and unfortunate associations inherent in the terms 'hysteria' or 'hysterical', and is defined as:

A. Behaviour that is over-dramatic, reactive, and intensely expressed, as indicated by at least three of the following: (1) Self-dramatisation, e.g. exaggerated expression of emotions; (2) incessant drawing of attention to oneself: (3) craving for activity and excitement; (4) over-reaction to minor events; (5) irrational, angry outbursts or tantrums.

B. Characteristic disturbances in inter-personal relationships, as indicated by at least two of the following: (1) perceived by others as shallow and lacking genuineness, even if superficially warm and charming; (2) egocentric, self-indulgent, and inconsiderate of others; (3) vain and demanding; (4) dependent, helpless, constantly seeking reassurance; (5) prone to manipulation suicidal threats, gestures, or attempts.

The aim of the present study was to describe how the category of hysterical personality disorder is used as a diagnosis; it was in two parts—a retrospective case note study and an experimental study. The first examined the use of the diagnosis in a clinical situation, the criteria on which it is made, and its effect on subsequent management. The experimental study investigated the process of diagnosis, using videotaped interviews, where the information available to the raters was presented in three separate extracts, each controlled for duration and content. The ratings made by the psychiatrists are examined to describe the patterns of diagnostic behaviour for each patient, in order to identify the underlying criteria for the diagnosis.

Preliminary study

The preliminary study describes the characteristics of a sample with the diagnosis of hysterical personality disorder. From a total of 1129 patients discharged from the Department of Psychiatry, Withington Hospital, Manchester in 1975, 52 received this diagnosis without any secondary one, and composed the sample. An item checklist was drawn up from an examination of ten case notes, taken at random. The information retrieved covered those clinical features on which the diagnosis appeared to be based, and included details of the patients's demographic characteristics, recent and past psychiatric and medical history, mental state findings, and subsequent management.

The case notes of all patients were retrieved and the data extracted on to the item checklist. Mean age of the sample was 37.1, s.d. 12.6 years; the sex ratio was 83% female, 17% male. These findings are comparable with other studies (Slavney & McHugh, 1974; Reed, 1975).

The mental state findings are summarised in Table I, and include all recorded abnormalities. A finding of particular interest is that 27 patients, i.e. about half of the sample, were not described with any of the core behavioural traits for hysterical personality disorder.

TABLE I

Findings on Mental state Examination and in continuation sheets of 52 patients diagnoses as hysterical personality disorder

	Index admission	*Past admission*
Depressed	31	3
Anxious	20	1
Aggressive	18	8
Unco-operative	10	3
Attention seeking	10	7
Histrionic	10	5
Suicidal	10	3
Manipulative	6	1
Evasive	6	1
Labile	5	2
Dramatic	5	2
Violent	3	1
Amnesia	3	1
Gansering	2	0
Hostile	2	0
Dependant	1	1
Belle indifference	1	0
Suspicious	1	1
Seductive	1	0
Egocentric	1	0
Immature	1	1
Suggestible	0	0

Examination of the case notes revealed a requirement for an additional diagnosis in half of the sample: these diagnoses were arrived at using conventional operational definitions where appropriate, but confirmed by an independent assessor. Nine patients suffered from alcohol or drug addiction, four suffered from depression with three or more biological symptoms, eight from epilepsy, three from hysterical neurosis, and two from a toxic confusional state.

The association with affective disorder was evident, both from the mental state findings and from the psychiatric history; 23 patients had a history of affective disorder, 12 described depression as their main presenting complaint, and 31 were described as depressed and ten as suicidal by the admitting doctor. A history of one or more overdoses was present in 38, and self-mutilation in 14; four were assigned an additional diagnosis of primary depressive illness by the criteria of Feighner *et al* (1972). In contrast, only nine patients received antidepressant medication and two had been treated with ECT.

Experimental study

Method

In the experimental study, two patients from the hospital sample were selected and invited to take part in a semi-structured videotaped interview. This consisted of three parts; the first extract, lasting one minute, included no clinical material, taking the form of a discussion about a neutral topic, e.g. a recent holiday, which simply allowed the viewer to see and hear the patient. The second extract, lasting 6 minutes, focussed on the patient's interpersonal difficulties, at the time of the index admission and during the subsequent 5-year period up to the present study; a detailed description was elicited of the patient's behaviour towards others—under usual circumstances and at times of stress. The final extract, lasting one minute, provided a vignette of the patient's presentation at the index admission, with relevant mental state findings, but without giving a diagnosis. Videotaped interviews of an identical format were prepared for two control patients who had been discharged in the same year, with diagnoses of an organic psychosis and a manic-depressive psychosis respectively.

The videotapes were shown to 14 psychiatrists, of varying seniority, who were unaware of the nature of the study. The order of presentation was: (a) hysterical personality disorder, (b) control, (c) control, (d) hysterical personality disorder. The videotape was stopped after each extract, and the psychiatrists asked to make their ratings. Each set of ratings consisted of an attempt at diagnosis, with the provision for a maximum of two alternatives allowed at each point, together with ratings on a scale of 0 to 10 for eight behavioural traits, presented as the following bipolar adjectival pairs: labile/stable, seductive/modest, dramatic/phlegmatic, hostile/friendly, immature/mature, anxious/relaxed, depressed/elated and dominant/submissive.

Results

The experimental study recorded the diagnostic behaviour of the rating psychiatrists, when making ratings of the four videotaped interviews for the two index hysterical personality disorders from the hospital sample and the two control patients. The first set of results focussed on the diagnoses made. Each of the 14 psychiatrists could make up to a maximum of two diagnoses after each extract, and therefore the maximum number in each cell was 28.

TABLE II

Number of diagnoses made by 14 psychiatrists allowed up to two diagnoses at each stage of viewing four videotapes. (Maximum number in each cell = 28)

	Recent holiday	*Interpersonal relations*	*Clinical details*
HPD	28	26	26
Control	9	16	20
Control	7	18	22
HPD	23	27	26
Comparison index with control groups	$P<0.01$*	$P<0.01$*	$P<0.05$

*Mann-Whitney U-Test

Table II shows that the number of psychiatrists making any diagnosis was significantly greater for the two index patients at the 1/1000 level. A significant difference between the two groups was most evident following the first extract, where one of the index patients actually received 28 diagnostic attempts—the maximum number possible.

TABLE III

Number of diagnoses of the general category of personality disorder made by 14 psychiatrists allowed up to two diagnoses at each of the three presentations. (Maximum number in each cell = 28)

	Presentation		
	1	*2*	*3*
HPD	7	17	18
Control	4	2	0
Control	1	8	5
HPD	8	11	16
Comparison of HPD with control groups	$P<0.1$*	$P<0.1$*	$P<0.01$*

*Mann-Whitney U-Test

The results presented in Table III refer to the number of diagnoses awarded for the general category of personality disorder. Any category of personality disorder was included in this figure, the data being reduced to the three figure ICD code—i.e. 301. The two index patients were again assigned a significantly greater number of diagnoses of personality disorder, the difference becoming strongest following presentation of the third extract.

TABLE IV

Number of diagnoses of hysterical personality disorder made by 14 psychiatrists at each of the three presentations (maximum number in each cell = 14, see text)

	Presentation		
	1	*2*	*3*
HPD	4	8	8
Control	1	1	0
Control	0	2	3
HPD	0	1	1
Comparison of HPD with control groups	NS	$P<0.5$*	NS

*Mann-Whitney U-Test

Table IV records the number of diagnoses of hysterical personality disorder, given after each extract. In this analysis, the denominator is 14, this being the maximum number of identical diagnoses that could be given by the 14 rating psychiatrists at each rating point. Comparing the number of diagnoses of hysterical personality assigned to the index and control patients, the results failed to reach a consistent statistical difference. One index patient received only two diagnoses of hysterical personality disorder, whilst one of the control patients received five diagnoses of the disorder.

TABLE V

Inter-rater reliability scoring behavioural traits—(Kendall's Coefficient of Concordance

		Presentation		
Trait	*Overall*	*1*	*2*	*3*
Depression	0.62	0.76	0.61	0.63
Anxiety	0.15	0.28	0.13	0.03
Immaturity	0.57	0.50	0.48	0.53
Dramatic	0.36	0.30	0.35	0.44
Seductive	0.28	0.20	0.39	0.15
Dominant	0.41	0.37	0.42	0.29
Hostility	0.78	0.70	0.87	0.87
Lability	0.25	0.02	0.22	0.23

At each rating point, concurrent with attempting a diagnosis, the psychiatrists made ratings for each of the eight behavioural traits. Comparing the two index and the two control patients, analysis of the ratings revealed the index patients to be rated as significantly more depressed, immature, dominant, and hostile after each videotaped extract.

From an examination of the diagnoses made during the videotaped interviews, it is apparent that the diagnosis of hysterical personality disorder was made on a total of 26 occasions. The results can be examined to identify the behavioural traits that are rated as present when the psychiatrist assigned the diagnosis of hysterical personality disorder, whether to an index or a control patient. Extracting the data for the 29 points where a diagnosis of the disorder was given shows that the patient is then rated as more immature, dramatic, seductive, and labile, all at the 1/100 level of statistical significance.

The inter-rater reliability for each trait was calculated using Kendall's coefficient. Although the reliability improved as more information was provided, the core traits of the hysterical personality disorder—seductiveness, dramatic lability and immaturity-remained unacceptably low (Table V).

Discussion

Patients receiving a hospital diagnosis of hysterical personality disorder are markedly heterogeneous, suffering from affective disorder, alcohol and drug addiction, epilepsy, and toxic confusional states. Despite the obvious diversity of the sample, there are particular features that single out patients for inclusion in this diagnostic category: the results of this study suggest that a major contribution derives from the mental state findings, which characteristically describe the patient as aggressive, unco-operative, attention-seeking, histrionic, manipulative, and evasive. Characteristics of the 52 subjects bear a close resemblance to those described by Forrest (1967), as shown by patients who do not comply with the hospital regime and are seen as difficult and demanding. However, it is remarkable that 27 patients were diagnosed as 'hysterical personality disorder' without one single core trait of the disorder being recorded in the case notes.

In keeping with the findings of Reed (1975) and of Slavney & McHugh (1974), there is a marked association with affective disorders, particularly primary depressive disorder. A second and more disturbing conclusion is that awarding the diagnosis of hysterical personality disorder distracts the doctor from formally recognising other significant psychopathology. This is reflected in half of the sample, where careful inspection of the case notes revealed evidence of an additional diagnosis. Similarly, the relatively meagre prescription of antidepressant treatment would indicate a failure to translate the recorded features of depression which were noted on admission into adequate treatment for the depression. This closely resembles the findingsof Bibb & Guze (1972), who reported a retrospective study of patients with Briquet's syndrome, where 80% of the sample was hospitalised for depression, yet the index cases were less likely to receive ECT than the controls.

The present experimental study examined the process of diagnosis in a situation where the psychiatrist might be presumed to be on his best diagnostic behaviour. The patient sample was very small, but the problems of persuading a group of psychiatrists to sit through a series of long videotapes prevented a more elaborate study.

The results indicate a significantly greater number of total diagnoses accorded to the index patients, most evident after a 1-minute video extract of the patient's appearance and behaviour during a clinically neutral interview. This observation compares with that of Kendell (1973) on 28 psychiatrists rating diagnostic interviews presented in three different formats—videotape, audiotape, and transcript; ratings were made at 2 minutes and 5 minutes. Comparing these ratings, the second interview showed an increase in the frequency of diagnoses for psychotic illness, with a corresponding fall in those of neurotic conditions: one may speculate that the increased amount of verbal and non-verbal information generated by the two index patients resulted in a more rapid diagnostic process and decision, resulting in a relative under-diagnosis of functional psychiatric illness and a parallel over-diagnosis of personality disorder.

One of our index patients achieved a respectable level of agreement amongst the rating psychiatrists as a genuine case of hysterical personality disorder, obtaining in total 20 such diagnoses. The other received only two diagnoses of hysterical personality disorder, and was not rated as having its core behavioural traits. Nevertheless, there are features common to both index patients which contribute to an understanding of why they received this hospital diagnosis. Both were rated as significantly more depressed, dominant, immature, and hostile, and their behaviour during the first extract of a one-minute interview had features that encouraged the psychiatrists to make significantly more diagnoses without adequate clinical information.

When assigning the diagnosis of hysterical personality disorder to either an index or control patient, the psychiatrists rated the patient as seductive, labile, dramatic, and immature; this finding is consistent with the classical description. It suggests that in an experimental situation, those assigning such a diagnosis have accurately assimilated the pattern of behavioural traits. On the other hand, having assigned the diagnosis, the psychiatrists may have simply rated what they believed should be seen. Either of these explanations would indicate that the psychiatrist has an accurate internal model of the behavioural traits classically described in the hysterical personality disorder.

Examination of the inter-rater reliability reveals a low coefficient of concordance for the core traits—dramatic, seductive, and labile—despite the videotaped interview focussing on areas of interpersonal difficulties which might be supposed to elicit such behavioural traits. So far as the surprisingly low inter-rater reliability for the trait of anxiety is concerned, it must be presumed either that the interview did not address itself to this trait, or alternatively that the actual recording of the interview in a studio produced anxiety in the patient that was interpreted differently by the psychiatrists.

Conclusion

The diagnosis of hysterical personality disorder is frequently made without the core features being present: over half of this hospital sample had none of the features of the disorder recorded in the case notes, and 50% of the patients had some other diagnosable condition. Two influences emerge from the present study that would seem to account for these findings. The first involves the use of the diagnosis to label those patients who are perceived as hostile, difficult, and unco-operative, with the result that the doctor is distracted from recognising an underlying diagnosis. By their very nature, the core traits of 'dramatic' and 'attention-seeking' indicate a performance that is overtly unconvincing and being played out by the patient; the availability of a recognised diagnostic category may allow doctors to resolve their negative feelings toward such patients. Yet these behaviours should cause doctors to try and understand the underlying problems, rather than attributing them exclusively to a long-standing character disorder. The second factor has not previously been identified; it is that patients with a hospital diagnosis of hysterical personality disorder have a set of characteristics that encourages psychiatrists to make diagnoses on wholly inadequate information. These characteristics were most evident in the first one-minute extract, and apparently consist of an excess of non-verbal behavioural cues, which lead to rapid and perhaps premature diagnostic decisions. The contribution of these two factors, translated into the clinical situation, may well account for the excessive use of the diagnosis reported by Walton & Presley (1973).

The definition of 'Histrionic Personality Disorder' in DSM-III may be helpful in answering some of the problems associated with the diagnosis, yet this definition itself relies on the accurate recognition of such traits as self-dramatisation and attention-seeking behaviour, which in this study have been found to have a low inter-rater reliability. Until these issues have been resolved, the diagnosis should be avoided; patients with undeniably genuine psychopathology may then be assured of an assessment not clouded by judgements about the peculiar nature of the personality traits.

Brief Reports

Deliberate Self-harm and Predictors of Out-patient Attendance

Kreitman (1979) reported that up to one-half of patients given out-patient appointments one week after an episode of deliberate self-harm (DSH) fail to attend, and gave a number of possible explanations for this. Firstly, parasuicide is often the result of a crisis which may have resolved (albeit temporarily) by the end of a further week. Secondly, someone in a state of heightened tension may find one week too long to wait, and may resort to other strategies to deal with his problems. Thirdly, many parasuicides may find a psychiatric label unacceptable in the context of their problems, and fourthly, an appointment made for a fixed day and a fixed hour may not fit the need for immediate action which the subject's subculture had inculcated in him as a habit pattern. Morgan *et al* (1976) reported that up to 40% of their DSH patients either did not attend any appointment or failed to complete their treatment. Two possible explanations for this were that they either felt that they did not need psychiatric treatment, or else believed that psychiatric treatment was not an answer to their problems. Kessel & Lee (1962), probably in line with much psychiatric practice, did not give a follow-up appointment to 40% of their self-poisoners; this was for two reasons. Firstly, these patients did not have a problem for which psychiatric treatment was appropriate and secondly, many of these patients had an entrenched personality disorder, which made it unlikely that psychiatric intervention would be beneficial.

Our study was designed to discover potential predictors of non-attendance. All consecutive referrals were given automatic out-patient appointments, with visits arranged at one week and one month after their DSH.

Method

All consecutive adult DSH referrals in a district general hospital in Newcastle upon Tyne were seen; it is still the policy of this hospital for all DSH cases to be referred to the psychiatric service for assessment and disposal. In addition to a standard psychiatric interview each patient was investigated with the following diagnostic and rating instruments: Suicide Intent Scale (Pierce, 1981); Newcastle Diagnostic Scale (Carney *et al*, 1965); Research Diagnostic Criteria (Spitzer *et al*, 1978); Hamilton Rating Scale for Depression (HAMD) (Hamilton, 1960) the 17-item version.

All patients received the standard psychiatric interview, and were investigated on the various scales at initial interview. At the one-week and one-month follow-up of those referred to out-patients', the RDC and HAMD were again completed. In offering patients follow-up, it was explained to them that this was both to assess their progress and also to help them deal with any problems they might have. Patients were followed-up by the assessor who originally saw them. A total of 98 patients were seen, of whom 80 were overdose takers, 14 self-mutilators, and four were both.

Twelve patients were admitted to a psychiatric unit, and the remaining 86 each given a psychiatric out-patient appointment; these 86 formed the subject of this study. They were given an appointment one week after their initial interview; those who attended at one week were given a further appointment at one month. Those who failed to attend at one week were sent a follow-up appointment at one month.

The statistical methods used were the χ^2 for categorical variables and the t-test for continuous variables.

Results

At one week, the attendance rate was 40%. At week four, attendance for the total sample was 31%. There were no significant differences between the attenders and non-attenders on the following items: marital status, state of marriage, children to the marriage, presence or absence of financial stress, history of Court appearances, employment status, history of unhappy childhood, early parental separation (under 15 years of age), and early parental death (under 15 years of age). There were also no significant differences with age, although there was a trend for a fall in the rate of attendance with increasing age. The two groups also did not differ significantly on the following items: past psychiatric history, past overdose, past laceration, psychiatric history in the family, and illicit drug use. With regard to psychiatric diagnosis there was once again no significant difference between attenders and non-attenders on various RDC categories, as shown in Table I.

A crisis situation preceding the DSH was also not predictive of attendance at follow-up: 42% with a crisis situation attended (similar to the overall attendance rate of 40%).

TABLE I

Category	*Attendance rate*
Mental disorder present	40%
No mental disorder	42%
Personality disorder present	41%
No personality disorder	29%

With regard to initial score on the Suicide Intent Scale, once again there was no significant difference between the attenders and non-attenders: Only 53% of patients with DSH rated as having been of serious intent came for out-patient follow-up. As to initial score on the HAMD, only 22% of those who scored 18 and over attended for follow-up.

On the Newcastle Depression Scale, 40% (five patients) of those with a diagnosis of endogenous depression attended (although the numbers were too small for any significance to be attached to them, compared to 39% with a diagnosis of neurotic depression—once again a non-significant difference between attenders and non-attenders.

Discussion

A working hypothesis which suggested itself to us before we commenced our study was that the patients who were more likely to be non-attenders would be those who were younger, who had a personality disorder, and who did not suffer a psychiatric illness. Our findings did not confirm this. On no major item investigated did we find clear-cut differences between those who attended and those who did not. A failure to attend applied equally to those with a psychiatric disorder, with clear symptoms of depression, and who had a high intent score, as it did to those without mental disorder or depression, or who had a low suicide intent score at initial interview.

Although we have not been able to identify the characteristics of those who failed to attend out-patients, our findings may well suggest that a different approach to the management of post-DSH patients may be required. Some patients may not see their problems in psychiatric terms (Kreitman, 1979), so that help from other professionals such as a social worker may be more appropriate—and this also suggests itself from the fact that most cases of DSH occur in the setting of social and interpersonal problems. Kreitman also suggested that attendance one week after the DSH may be too long for a patient to have to wait for help with his problems—an appointment within 2 or 3 days may therefore be more appropriate—and that seeing the patient away from the hospital setting, possibly at home, may improve the delivery of help offered to him. In this setting, the skills of a social worker or a community psychiatric nurse may be usefully applied, and such an approach would also be useful for a number of patients the psychiatrist would have wished to see at his clinic, but who default on this attendance. However, the early involvement of the general practitioner for the latter would also be valuable, more especially for the elderly depressive who may be at greater risk of suicide (Stengel, 1970). For the latter, the general practitioner and psychiatrist should liaise closely, in the event of the patient requiring either admission or a psychiatric domiciliary visit.

Khat-induced Paranoid Psychosis

For many hundreds of years the fresh leaves of the Khat shrub have been used for their stimulant properties. Several million people in East Africa and Arab countries chew the fresh leaves and with the growth of rapid air transportation the habit has spread.

Cathinone is considered the most active ingredient and has been recently isolated and synthesised (United Nations Document, 1975). The effects of cathinone closely resemble those of amphetamine (Halbach, 1972), to which it is chemically related. Regarding the beneficial effects of Khat, Carothers wrote in 1945:

> The chewing of this weed induces a happy and mellow friendliness and an increased intellectual vigour and acuity, thought tends to rise to a high plane, desire for war and women ceases, and conversation tends to concern itself with 'the affairs of God' and the accumulation of wealth by peaceful trade.

Amphetamine like sympathomimetic stimulation occurs with elevated blood pressure, mydriasis, hyperthemia, anorexia, insomnia, increased arousal, elevated mood and loquacity (Halbach, 1972).

Khat abuse may cause psychic dependence (Eddy *et al*, 1965), aggressive behaviour, paranoid ideation and ultimately personality disorders (Kalix, 1984). It may cause manic psychosis (Carothers, 1945; Laurent, 1962; Giannini & Castellani, 1982), similar in many features to that which may be induced by amphetamines. A North Africán student, in the United States developed a manic psychosis following ingestion of Khat which he had grown in his own apartment (Giannini & Castellani, 1982).

Case Report

F. K. a 34-year-old Somali woman was admitted to a medical ward following an overdose of propranolol, paracetamol and choroquine. She is a part-time student, separated from her husband and two children since 1978, who lives alone in a Council flat. She had no significant past medical history and there was no history of past psychiatric illness either in herself or in her family.

When seen on the medical ward she was noted to have paranoid delusions and evidence of thought broadcast which took the following form. Over several weeks prior to admission she had felt convinced that there were microphones located on the stairway leading to her flat which were repeating her thoughts. She felt she was being watched and followed and a searchlight was focussed on her flat monitoring her activities. She reported that the television repeated her thoughts. During these weeks she was chewing Khat every day and on the day of admission had chewed it for 8 hours. Prior to admission she had noted a loss of appetite and said she had not slept for 48 hours. She had felt that everything built up inside her to such an extent that she took the overdose.

At this stage insight was completely lacking, and she was still actively suicidal, but her mental state was otherwise normal. She was noted to have a mild otitis media which was treated with antibiotics. Full blood count was normal, a chest X-ray showed evidence of a little right basal shadowing and atelectasis consistent with infection, and a urine drug screen taken 9 days post-admission showed evidence of morphine and dihydrocodeine. From the second day she was prescribed trifluoperazine 5 mg three times daily which she took regularly for 5 days and intermittently thereafter. She remained severely paranoid for 11 days after admission but on day 12 her mental state had reverted to normal and she was discharged shortly afterwards. We felt it probable that the trifluoperazine had been a contributory factor in her recovery.

She returned to be seen on the ward 3 weeks after discharge bringing a sample of Khat which was identified by the Regional Poisons Unit. Her mental state was quite normal at that stage.

On a recent visit she admitted to having used Khat on occasions since her admission 4 months ago. She still felt at times her activities were being monitored and felt there were possibly microphones on the stairway. However, she described that when she chewed Khat these feelings intensified and on enquiry, were found to be fully delusional. Indeed, after taking Khat on two occasions since discharge she has again felt like taking an overdose.

Discussion

We were unable to fully explain the positive urine test for morphine and dihydrocodeine. The urine test may remain positive for up to 4 days following ingestion, which would indicate she may have taken these substances while on the ward. She adamantly denied use of these substances and was not prescribed any compound containing them.

The case of F. K. serves to highlight the importance of knowledge of Khat use in the United Kingdom. Use of Khat has serious socio-economic consequences in that Khat users harm their families by neglect, dissipation of family income and by their inappropriate behaviour (Kalix, 1984). It may cause a functional psychosis following consumption of exceptionally potent material or in predisposed persons (Kalix, 1984).

Finally, although this is the first case known to the Regional Poisons Unit, it is likely that greater awareness of the problem may result in other cases coming to light. It is the impression of F. K. that extremely large numbers of the Somali community in London (approximately 4000) use Khat and this is likely to represent only a proportion of the problem. In the case of F. K. Khat appears to have induced a full-blown paranoid psychosis with the added complication of a suicide attempt.

Down's Syndrome with Mania

Sovner *et al* (1985) proposed that the presence of Down's Syndrome (DS) precludes the possibility of concomitant mania, and this is not a new claim, since Earl (1961) had stated that neither cyclothymia nor manic-depressive psychosis occurred in the mentally retarded. While Sovner *et al* conceded that cases of mania in individuals with DS may simply have gone unrecognised or unpublished, they felt this to be unlikely. However, lest this suggestion enter the canon,. we present a previously unreported case of a young adult with both DS and recurrent mania.

Case report

A moderately mentally retarded, 23-year-old man was brought to a university psychiatric clinic by his mother because she was concerned about his increasing activity, increasingly grandiose ideas and decreased sleep. Down's Syndrome had been previously diagnosed on the basis of physical stigmata at examination, as well as trisomy 21 on chromosomal analysis. There was no family history of psychiatric illness. The patient had had a similar episode 2 years previously, characterised by increased hyperactivity, increased rate and volume of speech, and decreased appetite and sleep. Thioridazine treatment was instituted at that time, following which the patient became somewhat sedated; the symptoms had remitted within a month.

Two months before the most recent referral, the patient had once again shown increasing levels of activity and impulsivity and his mother had been forced to restrict him to the home because he had wandered off and almost got lost. His deteriorating behaviour was accompanied by a preoccupation with grandiose delusions, including that of his becoming a famous musician. He also became increasingly irritable, particularly when his grandiose ideas were challenged. Physiological changes included decreased appetite, a weight loss of 9 kg (20 lb), and decreased sleep. On each of the two nights immediately before being seen, he slept at most 2–3 hours, and was reportedly dancing and singing when awake, although it was in the middle of the night.

When seen, the patient was dressed like a certain pop singer, and demanded to be called by that singer's name, stating that the examiner was a television producer interviewing him for a job. The patient's affect was characterised by rapid swings from elation to irritation, when his mother did not respond to his grandiose statements, but when not challenged, he was most engaging. The examination revealed no evidence of hallucinations or mood-incongruent delusions. The physical, neurological, and laboratory examinations were all within normal limits, while a cardiology consultation revealed no change in the patient's asymptomatic ventricular septal defect with intraventricular and intra-atrial conduction defects.

The diagnosis was made of bipolar affective disorder, manic with mood-congruent psychotic features (DSM-III). This diagnosis was later confirmed independently by two attending psychiatrists.

Discussion

Mania and DS can and do occur concomitantly, as this case illustrates; there is a strong suggestion that ours is not the first report of this coincidence. Although not designated as cases of 'mania' (perhaps because of the then-prevailing diagnostic criteria), Rollin (1946) described a behaviour change, frequent among 'mongols', in which patients underwent

> a period of excitement amounting in some cases to an almost manic phase. They became wild, noisy and restless, talking incessantly, emitting weird animal noises or inarticulate gibberish. This phase passes after a variable interval, only to recur without any obvious cause.

Information in Rollin's three case vignettes is not sufficient to diagnose mania retrospectively, but it is of interest that one patient was noted to have become irritable and 'talked incessantly all day'.

Although unipolar mania and bipolar affective disorder may be less prevalent than unipolar depression in individuals with DS, this case shows that the two disorders are not mutually exclusive. However, much remains unknown about the incidence and prevalence rates of psychiatric disorders in DS, as well as in other types of mental retardation. If the prevalence rate of bipolar illness in DS is indeed less than in control populations, interesting possibilities are posed for further investigation of genetic predisposition to and protection from psychiatric illness.

Sovner *et al* (1985) have suggested an explanatory hypothesis for mania being incompatible with DS—that alterations in monoamine activity inhibit the development of mania—but present understanding of the pathophysiology of both conditions is too limited to support the contention of mutual exclusiveness.

In fact a case can even be made for a heightened association of DS and bipolar affective illness. Prange *et al* (1974) hypothesised that low indoleamine activity 'permits' development of mania, when it is present with elevated catecholamine activity. In subjects with DS, blood 5-hydroxyindole levels (Rosner *et al*, 1965; Tu & Zellwegger, 1965) and serotonin uptake into platelets (Boullin & O'Brien, 1971) have been reported to be decreased, compared with controls. According to Prange's hypothesis, this should lead to an *increase* in the incidence of mania in individuals with DS, but as yet, too little is known of the biology of both DS and mania: there are still contradictory data. For example, CSF 5-hydroxyindoleacetic acid levels in patients with DS have been found *not* to differ from those of neurological controls (Lott *et al*, 1972, Tu & Partington, 1972).

Epidemiological studies of psychiatric illness among the mentally retarded have been only limited; as a whole, they suggest that such illness is at least as prevalent as in the general population (Parsons *et al*, 1984). Psychiatric diagnosis in the mentally retarded illustrates the importance of diagnosing each case on the clinical data, rather than on theories of pathogenesis (Sovner & Hurley, 1983).

Capgras Syndrome in a Patient with Dementia

The Capgras syndrome was first described as an 'illusion of doubles' in 1923 by two French psychiatrists, Capgras and Reboul-Lachaux. Since then, a number of cases have been reported of this syndrome co-existing with functional as well as organic disorders. Enoch & Trethowen (1979) regarded the syndrome as purely functional—a manifestation of schizophrenia. Recently, there have been case reports describing the occurrence of Capgras syndrome with diabetes (MacCallum, 1973), hypothyroidism (Madakursira & Hall, 1981), hepatic encaphalopathy (Pies, 1982; Cummings, 1985), pseudo-hypoparathyroidism (Hay *et al*, 1974), temporal lobe epilepsy (Chawla & Virmani, 1977) and vitamin B12 deficiency (Zucker *et al*, 1981).

The following report discusses the presence of Capgras syndrome in a patient with dementia.

Case report

A 73-year-old married woman was referred for evaluation of her memory problem. Her husband complained that it was difficult to manage her because she told him "You are not my husband but an impostor". This delusional misidentification persisted, occasionally only for hours, sometimes for days. During the episodes, her husband tried to persuade her of his identity by showing her photographs and reminding her of their earlier life, but without success.

On mental state examination she was not hallucinating, but her memory and orientation were impaired. There was no evidence of depressive disorder and she had no suicidal ideas. At the clinic, she was able to recognise her husband; but when reminded of her earlier statements, she again expressed occasional suspicions that he might be an impostor. She had insight into her memory impairment, and became very anxious and upset when she could not perform well in tests. Blood biochemistry, including T_3, T_4, serum B12 and folic acid, was within normal limits. Electroencephalographic and computer axial tomographic scan findings were consistent with a generalised degenerative process. Most probably, she was suffering from dementia of the Alzheimer type.

The Capgras phenomenon persisted on and off during an 8-week follow-up period. As the patient's husband was coping satisfactorily, prescription of psychotropic medication was postponed.

Discussion

Reports of the Capgras delusion co-existing with various brain lesions or with metabolic and endocrine disorders are appearing with increasing frequency. Although some authors (Hayman & Abrams, 1977; Alexander *et al*, 1979; Quinn, 1981) have suggested that the syndrome is commoner in localised right than in left hemisphere disease, the present report is the first which suggests that Capgras features can also accompany a general degenerative disorder of the brain such as dementia of the Alzheimer type.

It is difficult to establish that the Capgras delusion is caused by an organic state, and the simultaneous occurrence of both in one patient may be coincidental. However, it would seem desirable in all cases of Capgras syndrome to investigate thoroughly for an organic pathology. It also seems that the syndrome is not as specific to schizophrenic or affective psychosis as has been suggested in the past.

A Pilot Study of Phenelzine in the Treatment of Post-traumatic Stress Disorder

In recent years, there has been renewed appreciation of the morbidity which can result from unusual or overwhelming stress and while many situations can give rise to post-traumatic disorder, the most frequently studied of these is probably military combat. Psychiatric disorder pursuant to combat experience can not only become chronic, but may intensify with advancing age, decades after the original trauma (Archibald & Tuddenbaum, 1965; Wilmer, 1982). Moreover, a high percentage of combat veterans are believed ultimately to develop chronic psychiatric morbidity (Walker & Cavenar, 1982). The drug treatment of such post-traumatic states remains an important question, largely overlooked until the last 2 years but recent case reports suggest that doxepin and imipramine (White, 1983; Burstein, 1984) are beneficial in treating post-traumatic stress disorder (PTSD), which may be either combat or non-combat related. Hogben & Cornfield (1981) described five veterans whose PTSD improved when treated with phenelzine, while Van der Kolk (1983) has described beneficial results with antidepressants, lithium, benzodiazepines, beta-blockers, and neuroleptics in uncontrolled studies of PTSD.

Having studied phenelzine in depressed inpatients (Davidson *et al*, 1978, 1981), depressed outpatients (Raft *et al*, 1981), and during long-term continuation treatment (Davidson & Raft, 1984), we decided to undertake a further study of phenelzine in PTSD. Our aim was to extend the earlier reports and to utilise quantitative measures of drug effect. We employed observer and self-rating scales, the latter being considered a useful counter-balance to any observer bias that might operate in an open study, particularly when a new drug indication is being explored and, permitting assessments of specific symptom complexes within PTSD. We present here the results of a pilot study of phenelzine in 11 veterans of World War II or Vietnam.

Method

During a 7-month period, all potentially suitable subjects were interviewed for the study. It was necessary for patients to meet DSM-III criteria for chronic PTSD, which are grouped into four distinct sets of items.

(a) Presence of a recognisable stressor that would evoke stress in almost everyone.

(b) Intrusive re-experiencing of the trauma, as shown by at least one of the following:
  (i) recurrent recollections of the event,
  (ii) recurrent dreams of the event,
  (iii) acting as if the traumatic event were recurring because of a reminder.

(c) Numbing of responsiveness to, or reduced involvement with the external world following the trauma, as illustrated by at least one of the following:
  (i) diminished interest,
  (ii) estrangement from others.
  (iii) constricted affect.

(d) At least two of the following symptoms that were not present before the trauma:
  (i) exaggerated startle or hyperalertness,
  (ii) disturbed sleep,
  (iii) guilt over survival or behaviour required for survival,
  (iv) impaired memory or concentration,
  (v) avoidance of reminders of the event,
  (vi) symptoms worse by exposure to symbols or reminders of the event.

In addition, we required that at least one key symptom each out of sections (b) and (c) be present to at least a moderate degree on a 0–4 rating scale, in which 0 = absent, 1 = mild, 2 = moderate, 3 = severe and 4 = extreme; we thus ensured that patients manifested at least a moderate degree of active symptoms. All patients gave informed consent for the study and receiving treatment as out-patients.

A dose of either 45 mg or 60 mg phenelzine was administered for 6 weeks, with a minimum of 4 weeks' treatment to complete the study. We chose a conservative approach to dosing, since there were no accepted guidelines for using phenelzine in this condition. No other psychoactive medicine was administered.

Patients returned for assessment at weeks 2, 4, and 6. All the rating scales were administered at each visit, and platelet MAO activity was measured at weeks 0, 4 and 6, by a method described by Davidson & White (1983).

To assess progress, we used three observer and three self-rating scales. One observer (J. I. W.) independently assessed the DSM-III features of PTSD, after which the patient was interviewed by another observer (J.D.) for assessment with the Hamilton anxiety and global improvement measures (Hamilton, 1959). Patients completed the Impact of Events Scale (IOES) of Horowitz *et al* (1979), which measures the intrusive ('positive') and avoidant ('negative') aspects of post-traumatic stress. Patients also completed a self-rated global improvement assessment. Treatment emergent effects were rated by JRTD, as a measurement of possible drug-related adverse events.

Anchor points on the global improvement scale were 1 = very much improvement, 2 = much improvement, 3 = moderate improvement, 4 = minimal improvement, 5 = no change, 6 = deterioration. These can be conveniently divided up into responder and non-responder groups, using ratings of 1, 2, or 3 to denote the former and ratings of 4, 5, and 6 for the latter.

The full dose of phenelzine was begun on the first day of treatment.

Results

Eleven patients entered the study, one of whom dropped out at week 2 because he did not wish to remain on the restricted diet. Ten patients completed 4 weeks' treatment, at which point two were removed from the study on account of poor response or deterioration, while another was removed because of side-effects. All subsequent analyses refer to those cases completing 4 or 6 weeks.

The mean age ± s.d. was 45.7 ± 12.8 years, the median being 39 (Table I). Five of those completing were veterans of World War II, and five of the Vietnam War. Nine patients received 45 mg phenelzine per day from the first day of treatment, and one 60 mg per day, which had to be reduced at week 4 due to side-effects.

Measures of efficacy

The degree of observed and self-rated improvement at weeks 2, 4, and 6 is presented in the Table I; 50% of the group were assessed as having responded by the two global improvement scales at week 2. At week 4, 70% of the group had responded to treatment according to the observer CGI, while 80% rated themselves as having responded on the self-rated CGI. Observed and self-rated responder rates at week 6 were 85% and 100%.

Platelet MAO activity was measured in nine patients at weeks 4 and 6. (It had not been possible to obtain a baseline value for the first patient.) The median levels of inhibition at weeks 4 and 6 were 81% and 85% respectively, while the three non-responders or equivocal responders (patients 5, 8, 10) showed inhibition values of 31, 48, and 80% at week 4. The responders achieved inhibition levels of 81, 100, 87, 92, 65, and 89% at week 4.

The observer ratings showed significant reduction of score, relative to baseline, using a paired two-tailed t-test for within-group differences. The DSM-III criteria score was 27.9 ± 6.5 at baseline, falling to 18.8 ± 7.4 at week 2 ($P<0.1$), 16.0 ± 7.7 at week 4 ($P<0.05$), and 13.2 ± 6.4 at week 6 ($P<0.1$).

The Hamilton anxiety score was 26.7 ± 6.9 at baseline, dropping to 15.7 ± 4.5 at week 2 ($P<0.05$), 15.7 ± 7.2 at week 4 ($P<0.02$) and 14.5 ± 3.5 at week 6 ($P<0.1$).

The amount of change in each symptom was examined with respect to week 4, calculating change as a percentage relative to baseline. Thus, if baseline score was 3, and the post-treatment score was 1, the percentage of improvement would be 66%. For the items in group (b), improvement for intrusive recollections, recurrent dreams, and acting as if back in combat were 61%, 42%, and 65% respectively. For the items in group (c), improvement in diminished interest, estrangement, and constricted affect was 37%, 56%, and 78% respectively. For the items in group (d), improvement for hyperalertness/startle was 39%, sleep disturbance 41%, guilt 44%, impaired memory or concentration 60%, avoidance of activities 18%, and symptoms worse with reminders 20%.

The self-rated IOES failed to show any evidence of change on either intrusive or avoidant items. The mean ± s.d. scores at each time point for avoidant items were 16.9 ± 4.9, 15.9 ± 4.7, 15.8 ± 5.1, 14.8 ± 6.7. The scores for intrusive items were 16.6 ± 3.8, 15.9 ± 5.0, 13.8 ± 4.1 and 16.4 ± 4.0.

TABLE I
Demographic information and response to treatment

Patient No.	*Age*	*Daily dose mg/day*	*Week 2*		*Week 4*		*% MAO*	*Week 6*		*% MAO*
			O-CGI	*SR-CGI*	*O-CGI*[1]	*SR-CGI*[1]	*Inhibition*	*O-CGI*[1]	*SR-CGI*[1]	*Inhibition*
1	60	45	1	4	2	2	NA	1	3	NA
2	58	45	DROPOUT							
3	32	45	3	3	1	1	81	3	3	85
4	39	45	3	4	2	3	100			
5	49	45	5	5	6	5	31			
6	59	45	5	4	2	3	87	2	2	98
7[2]	36	45	2	2	3	2	92	2	3	100
8[2]	59	45	4	2	4	3	48	4	3	86
9	35	45	4	3	3	3	65	2	3	30
10	31	45	4	4	4	4	80			
11	37	60	3	3	2	3	89	3	3	69
Median	39	45	4	3	2	3	81	2	3	85

1. Scores of 1 = very much improved, 2 = much improved, 3 = moderately improved, 4 = minimally improved, 5 = no improvement, 6 = worse.

O-CGI denotes Observed Clinical Global Improvement

SR-CGI denotes self-rated clinical global improvement

Scores of 1, 2, 3 are grouped as 'responders', scores of 4, 5, 6 are grouped as 'Non-responders'.

2. Coexistent major depressive disorder.

Treatment-emergent events

At each week, patients were questioned about the emergence of any new symptoms or complaints that had not been present prior to treatment, and note was also made of problems that appeared to worsen during treatment. Clinically significant events were reported by eight (80%) patients, who averaged 2.0 events per person. Most frequent and troublesome were intensification of pre-existing sleep disturbance (four patients), emergence of dizziness (four), and erectile failure (three). Other side-effects noted in one case each were delayed ejaculation, delayed urination, constipation, dry mouth, blurred vision, drowsiness, behavioural disinhibition, blackouts, perceptual changes, and hypomania.

The aggravation of sleep disturbance was especially troublesome, since sleep impairment had been a leading reason for treatment, having caused significant distress to patient and spouse. These treatment-emergent events necessitated dose reduction from 60 to 45 mg in one instance, and to treatment being discontinued in three others. From our previous experience with phenelzine (Evans *et al*, 1983), we had not expected to find so many problems with tolerance of this dose, but no serious or life-endangering toxicity occurred.

Discussion

This pilot study suggests promising effects of phenelzine in the treatment of PTSD, and thereby potentially extends further the application of MAO inhibitors in psychiatry. However, we should not automatically assume that the improvement which we saw was PTSD-specific, since many features of this condition are non-specific symptoms, also found in depression and anxiety (e.g. loss of interest, sleep disturbance, impaired concentration). It is therefore of interest to note that three out of the five symptoms which improved by greater than 50% were specific to PTSD: intrusive recollections, acting as if the trauma were recurring, and estrangement from others. Somewhat less improvement was noted on sleep, nightmares, startle, and guilt, although there was noticeable amelioration on these measures.

Our findings need to be followed by a double-blind placebo-controlled assessment of phenelzine, since it could be argued that we were merely observing placebo effects, e.g. most improvement occurred in the first 2 weeks. Furthermore, a placebo-controlled study would enable one to assess which particular symptoms were most drug-responsive.

The self-rated IOES failed to detect any drug effect, and we wonder whether it is unsuitable for measuring treatment effects, or if patients perhaps had difficulty in fully understanding the scale's wording. Yet another explanation is that secondary gain (e.g. disability pension) made patients reluctant to admit too much progress.

Forty-five mg of phenelzine is thought to be a borderline dose, and our MAO data suggest that one reason for poor response could have been insufficient dosing. On the other hand, an important finding was the high incidence of troublesome side-effects at the moderate doses used, thus making the dose of phenelzine itself a topic for further assessment in PTSD.

The findings can be speculatively related to recent animal studies which used an analogue of PTSD—the inescapable shock model. Weiss *et al* (1975, 1976) showed that both phenelzine and clonidine decreased the long-term effects of inescapable shock in rats. Since clonidine down-regulates locus ceruleus activity, and phenelzine results in a centrally mediated down-regulation of adrenergic activity, we are tempted to speculate that the effects of phenelzine in PTSD are also mediated through the locus ceruleus, and further evidence that it is of importance in PTSD comes from the successful use of clonidine in controlling the hyper-reactivity of PTSD (Kolb *et al*, 1984). Van der Kolk (1985) has proposed one association between positive symptoms and noradrenergic hyper-reactivity, and another association between negative symptoms and depletion of catecholamines. Further studies are clearly needed in order to understand the neurobiological basis for PTSD, and to integrate basic mechanism with treatment response.

Electroconvulsive Therapy and Cognitive Improvement in a Very Elderly Depressed Patient

A computer search of the literature revealed that the oldest documented patient to receive electroconvulsive therapy (ECT) was a 94-year-old woman (Bernstein, 1972) who was diagnosed as having 'anorexia nervosa', but the history was suggestive of paranoid schizophrenia. She received a course of five ECTs and became much less paranoid, ate well, and put on weight. Her daughter lamented the fact that ECT had been deemed to be contra-indicated 15 years earlier on the grounds of advanced age.

Depression in the elderly can be difficult to treat and relapse is common (Raskind, 1984). However, ECT appears to be at least as effective in the elderly as in younger depressed patients and it is also a relatively safe therapeutic tool in this age group (Weiner, 1982).

We now describe the treatment of a 91-year-old patient with ECT and report her improved cognitive state shortly after the treatment was completed.

Case history

E. D., whose ninety-second birthday fell on 5 May 1985, was referred for admission to our hospital by an outside psychiatrist attached to a general hospital because of 'failing cognition', 'dementia', and 'agitated behaviour'. Long term in-patient care was suggested. She had previously been admitted in September, 1984 to that hospital where she was treated by the referring psychiatrist for agitated depression with dothiepin hydrochloride and diazepam. She showed a 'slow, but steady, improvement' but her cognitive state was sufficiently suggestive of a dementing illness to warrant arranging the index admission on 15 March 1985 from the home for the aged at which she resided.

When she was admitted to our unit she was very depressed and agitated. She complained of feeling very weak and requested to be transferred to the 'Hospice for the Dying'. She had given up all hope of surviving, believed that she was not worth bothering with, and clutched to her rosary beads with fanatical strength. She was obviously in great psychological distress. A diagnosis of psychotic depression was made. On Day 1 of her admission she scored 18 on the Mini-Mental State test (Folstein *et al*, 1975; DePaulo *et al*, 1980), a test of cognitive function which can be repeated at intervals and wherein a score of less than 24 indicates cognitive disorder. It is a reliable and valid 30-point bedside examination (DePaulo *et al*, 1980).

Physical examination, apart from mild chronic obstructive airways disease and slightly reduced peripheral pulses, was unremarkable for a woman of her age.

The patient was suffering to such a great extent that we asked her if she would consent to ECT. She was unable to make up her mind and also believed that her doom was nigh. We approached her family who readily agreed to have her status changed from that of a voluntary patient to an involuntary patient—the latter is termed 'temporary' patient under our 1945 Mental Treatment Act, and they then signed a consent form for ECT.

E. D. received three applications of ECT on 22 and 27 March, and on 3 April 1985. The drugs used during the procedure were Brietal, atropine and Anectine. During the period of ECT administration she was put on prophylactic Septrin and Ventolin. She was slightly confused during, and for about 10 days after ECT. This cleared rapidly. She refused psychotropics for a week after ECT but then consented to take thioridazine 25 mg four times a day. Her depression and agitation had disappeared after the second ECT.

Serial Mini-Mental State tests were performed on 15 March (score = *18*) and on 4 April (*18*–24 h after 3rd ECT), 9 April (*22*), 10 April (*22*), 18 April (*23*), and on the day of her discharge, 1 May (*24*). She had obviously learned new material during the course of ECT since she constantly reminded us that she would pick the same items from her environment for memory testing as she had done previously. She took great pride in 'passing' the tests.

She had borne seven children, five boys remaining alive. One died at 14 months, cause uncertain, and another died at 12 years of age of a 'bladder complaint'. A 62-year-old son was a chronic schizophrenic in-patient of our hospital.

E. D. had experienced no previous serious psychiatric or physical problems before the onset of her recent depression. The latter we estimate to have started in December 1982. She improved with out-patient dothiepin over about 4 weeks and had maintained this improvement until some weeks before her first admission in September 1984.

Discussion

We have presented the case of a 91-year-old female, the second oldest in the literature to have received ECT, whose cognitive functioning improved following its administration.

Weiner (1982) points out that the effectiveness of ECT is not reduced when it is used to treat the elderly, and that if it is performed with appropriate precautions and modifications, it is a relatively safe means of treating severe depressive disorders occurring in this age group. It is not only more effective than drug therapies for many patients with severe physical illnesses, especially those with heart disease (O'Shea, 1985), but it may also be safer (Fink, 1979). Despite an increased frequency of medical problems, particularly affecting the cardiovascular system, ECT was still considered to be a safe procedure for elderly psychiatric patients in one study (Alexopoulos *et al*, 1984). Small & Mandel (1981) state that unilateral, non-dominant ECT results in transient memory deficits that are independent of the patient's age. They also state that ECT should be strongly considered in the treatment of elderly patients with endogenous symptoms who fail to respond to tricyclic antidepressants or who cannot tolerate their side-effects. Our patient received bilateral ECT—Bernstein (1972) does not give details on his 94-year-old, and she had refused to take psychotropic drugs.

In a retrospective review (Karlinsky & Shulman, 1984) of ECT in the elderly, the charts of 33 elderly inpatients (age range, 62–85 years) who received ECT in a psychogeriatric unit of a general hospital disclosed that ECT was safe but not uniformly effective. 42.4% of patients obtained an immediate good outcome. The authors felt that clinically one was still compelled to use ECT on an 'urgent and humane' basis.

In another study (Fraser & Glass, 1978) nine elderly depressed patients were given ECT in courses which alternated unilateral and bilateral electrode placement. Recovery took on average five times as long from unilateral treatment and nine times as long from bilateral treatment as had been found in younger patients. Bilateral treatment was significantly more sensitive to cumulative and interval effects in these elderly subjects. Their mean age was 72.4 years; s.d. 5.

Fictitious Epilepsy associated with Amnesia

Epilepsy can occur in patients without any changes apparent in the electroencephalogram. Thus the diagnosis of epilepsy is essentially made on clinical grounds. The clinical features of epilepsy are relatively easy to learn to mimic. Feigned epilepsy can occur in adulthood or it may occur in childhood, as part of a Munchausen syndrome by proxy as described by Meadows (1984). We would like to describe a case of feigned epilepsy with global amnesia, and several other symptoms of aberrant illness behaviour.

Case report

A woman of 30 years of age was admitted to the Royal Liverpool Hospital on 26 September 1984, brought to the Accident and Emergency Department via the Samaritans. She claimed that she had lost her memory, and alleged that she could not remember her name or any of her personal details. She said that she thought she was an epileptic, and in her handbag were bottles of anticonvulsants. Ward observers noted fits, some of which appeared genuine. Neurological examination following one such fit revealed weakness of the sixth cranial nerve and decreased sensation and weakness of the right side. Phenytoin and phenobarbitone were recommenced, and a Heminevrin infusion given for 6 days. Liver function tests revealed after 2 days raised liver enzymes: gamma-glutamyl transferase = 290 U/l (NR 0–65) and alanine amino transferase = 54 U/l, (NR 7–54). These continued to rise for 6 days to 580 and 280 U/l respectively, before gradually decreasing. She had a swinging pyrexia, and because of a history of a mastoidectomy, an ENT surgeon examined her, and prescribed antibiotics. An EEG and a repeat EEG showed no abnormality. Later she was seen holding a lighter near a thermometer. Suspicion was raised as to whether she was feigning illness and she was transferred to a psychiatric ward on the 18 October 1984.

She revealed that she had been a patient at the North Manchester General Hospital, and subsequent enquiries revealed she had been admitted there under the care of a physician in July 1984, and had only been discharged 7 days prior to her admission in Liverpool. The history then had been a very similar one of amnesia and epilepsy. As a result of her non-response, she had been prescribed an escalating dosage of phenytoin and had developed phenytoin toxicity. The character of her epilepsy was later thought to be feigned and some of the fits responded to placebo treatment. Numerous investigations including EEGs, a CAT scan and lumbar puncture proved negative.

Following extensive enquiries the following details of her personal history were obtained. She was born in Blackpool in 1954. Her father was a greengrocer, and she was their only child. She was enuretic until the age of 10 years and truanted from school. She left school at 15 and followed a pre-nursing course for one year. Her first child was born when she was 17. She married a soldier, but the marriage only lasted one year, and her second child, a boy, was born then. She worked over a long period as a taxi driver. She lived with her parents until 1980 and was drinking heavily. She had frequent contacts with the local hospital and attended various clinics, including ENT and gynaecology clinics. In 1980 she was admitted to a hospital in Blackpool following an overdose of alcohol and drugs. In November 1980 she was admitted to Lancaster Moor Hospital with a history of amnesia. Since 1980, when she left home, she has had numerous admissions to hospitals in Preston, Bolton, Leeds, Bradford, Chester, Rochdale and Manchester. She has used various names and had numerous investigations for her amnesia and fits. These include several EEGs, CAT scans, X-rays, blood tests, and lumbar punctures. These have shown no abnormality except for raised liver enzyme levels on some occasions. She is also known to have had five convictions, and was in Risley Remand Centre as recently as April 1984. At the time of her admission she was still on probation.

On admission to our unit, mental state examination revealed that her affect was bland and she appeared unconcerned about her memory loss. Formal testing of her short-term and long-term memory showed them intact. However she continued to maintain that she did not know her name or any of her personal details, except the odd titbit, e.g. she could remember being in a car accident, and that she had been divorced. There was no other cognitive defect or other evidence of mental illness. The nursing staff observed her to have some 'fits'—some of which appeared genuine, and at times she bit her tongue and was incontinent. On 24 October 1984 she presented the nursing staff with a sample of apparently blood-stained urine which she claimed to have voided. No physical cause of haematuria was found. On 19 November 1984 she went to the hospital's Casualty Department, giving a fellow patient's address. She complained of chest pain and an ECG was performed. She was on the point of being admitted to a medical ward, when she was discovered.

She was discharged on 19 December 1984 to a probation hostel in Liverpool. A few days later, on New Year's Eve, she again presented herself to the Casualty Department complaining of chest pains and haemoptysis. She was admitted to a medical ward with a suspected pulmonary embolus and heparin therapy commenced. When her identity was discovered a few days later she was discharged.

Comment

This case shows many of the typical features of a Munchausen syndrome (Enoch & Trethowan, 1979). The patient appears to be in an early phase of her career as a hospital addict; the best documented case so far being McIlroy (Pallis & Bamji, 1979). Although Munchausen Syndrome cases usually present with physical complaints, 'psychological' Munchausen Syndrome cases do exist as shown by feigned bereavements (Cremona-Barbaro, 1983). This case shows the co-existence of physical and psychological symptoms. The only physical abnormality found in this case were the raised liver enzyme levels. These findings are difficult to explain, but could be related to liver damage due to her past alcohol abuse, a recent bout of heavy drinking, or a paracetamol overdose such as she has taken in the past.

Management of Munchausen syndrome cases is extremely difficult, as it depends on the patient's motivation, which is usually concerned with more 'treatment'—they seek the mode of cure rather than the cure itself. It has been suggested that local casualty departments should be informed of such cases to aid in their detection. One possible solution is the setting up of a register, and with modern technology it would be relatively simple to keep a national database of such cases on a micro-computer.

Ephedrine Psychosis Rediscovered

The use of ephedrine for medicinal purposes dates back over 5000 years, when native Chinese physicians first used a herb, Ma Huang, which contained the active alkaloid. Ephedrine was extracted from

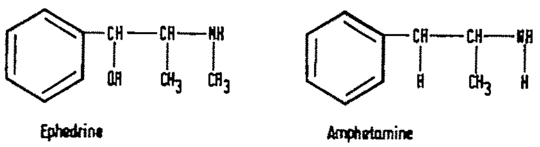

FIG. 1 Chemical structure of ephedrine and amphetamine.

Ma Huang in the late 1800s, but was considered too toxic for clinical use; it was rediscovered by Chen & Schmidt (1930), who demonstrated its sympathomimetic action and introduced it into Western medicine, where it was found to be a big improvement on adrenaline in the treatment of asthma. That the structure of ephedrine is very similar to that of amphetamine is not a coincidence, since Alles (1933) synthesised the latter as a synthetic substitute for ephedrine.

Herridge & A'Brook (1968) described two cases of ephedrine psychosis, stating that "so far as we can discover there have been no previous reports of psychosis following abuse of ephedrine." However, according to Otto & Nause (1980), "the appearance of psychoses following abuse of ephedrine has been known since the end of the 1930s and repeatedly described in the German literature in the 1940s. We report here a paranoid psychosis following increased use of ephedrine.

Case report

A 59-year-old single night watchman was brought to the casualty department by the police after entering a woman's flat uninvited. He had no history of psychiatric illness, alcoholism, or drug abuse, but had a long history of chronic asthma, for which he had taken ephedrine for 25 years; his personality was considered schizoid. There was no family history of psychiatric illness. Over the previous 2 weeks he had been working excessive overtime and had been concerned regarding recent thefts at his place of work. He was worried that he would be unable to apprehend trespassers because of his asthma and so doubled his ephedrine intake to 360 mg daily; this was taken as ephedrine hydrochloride plus 'Bronchipax' (ephedrine resinate 30 mg, theophylline 40 mg and salicyclamide 250 mg). Within 24 hours of this increase, he began to experience auditory hallucinations in the form of a woman's cries, and believed that a woman was being tortured in the flat below him. He made tape recordings of these cries and took them to the police, who did not believe him. He therefore took matters into his own hands and decided to search the flat for himself, alarming the female occupant, who called the police.

He was taken to the casualty department where he was seen by a psychiatrist and admitted under a compulsory order to a psychiatric ward. He described a 2-week history of auditory hallucinations and delusions, presenting in a setting of clear consciousness without mood disturbance. On admission, the dose of ephedrine was reduced to 60 mg. Ten days later, the patient was apparently symptom-free and was discharged, but he had been denying symptoms, and was in fact still experiencing auditory hallucinations. However, all psychotic symptoms disappeared 3 days later, and the patient gained full insight. He retrospectively described Schneiderian first-rank symptoms of thoughts spoken aloud and voices commenting on his actions and discussing him, which he had also been concealing from the staff during the psychotic episode.

Discussion

Psychosis associated with ephedrine use has been reported in a number of countries and there have been 20 case reports with adequate details. The reference to these cases are available on application to the authors.

Their ages range between 19 and 65 years. Ten were male and ten female. In only two cases was there a previous history of psychiatric illness: one patient suffered from 'neurasthenia' and another from panic attacks and hyperventilation. Only two patients had a family history of psychiatric illness, both their fathers being alcoholic. Three patients were considered to have an abnormal premorbid personality: one schizoid, one asthenic, and one obsessional. The most common reason for taking ephedrine was asthma, accounting for 60% of cases, although two asthmatics increased the dose for its stimulant effect. Two patients were drug abusers who had previously taken morphine, amphetamine and LSD, although not prior to the psychotic episode. Three patients took ephedrine purely for its stimulant effect, although they had not abused other drugs. Other reasons for taking ephedrine included hypotension, neurasthenia, and anxiety state with hyperventilation attacks where the patient believed that she was suffering from asthma. The length of consumption of ephedrine varied from 3 days to 25 years, with 80% of the patients having taken ephedrine for at least a year. In the majority of cases, the dose of ephedrine was gradually increased. The daily dose of ephedrine prior to the psychotic episode varied from 125 mg to 2500 mg, the average being 510 mg.

The main clinical features of the 20 cases are listed in Table I. The typical clinical picture is a paranoid psychosis with delusions and auditory hallucinations, in a setting of clear consciousness. This is very similar to amphetamine psychosis, with 45% of the patients experiencing visual hallucinations—a similar figure to the 50% in the report of amphetamine psychoses by Connell (1958). Clouding of consciousness was described in three patients and has also been noted in a minority of cases of amphetamine psychosis

TABLE I
Clinical features of patients with ephedrine psychosis (n=20)

(Ellinwood, 1969). Many patients had more than one episode of ephedrine psychosis, and one experienced recurrent episodes over a 10-year period. Two patients remained psychotic despite abstinence from ephedrine, and two developed chronic defect states.

In its typical presentation, ephedrine psychosis raises some theoretical problems regarding the nosology of 'symptomatic schizophrenia'. This was discussed in 1959 by Slater in his review of Connell's monograph on amphetamine psychosis: "It is a matter of much theoretical interest how closely a pseudo-schizophrenic symptomatic psychosis may resemble the true endogenous schizophrenia . . . It seems probable that with adequate attention to specific tests, a much larger number of patients would have shown evidence of some degree of clouding of consciousness". It was thought at that time that a toxic psychosis would manifest as an acute confusional state. Apart from Kendell's work (1975) and Davidson & Bagley's (1969) paper on schizophrenia-like psychoses further discussion of the nosology of 'symptomatic schizophrenia' seems to have been swept aside in the English speaking world by the advent of the American DSM classification with its atheoretical basis. However, the appearance of ephedrine psychosis in the 1930s in Germany led to a solution being proposed in 1956, with Wieck's description of the '*Durchgangs-Syndrom*' (translated as: 'passageway' and indicating a transitory state). This was based on Bonhoeffer's ideas of the non-specificity of psychiatric symptoms (Scheid, 1962), and described a reversible organic state, without clouding of consciousness and no 'obligatory' symptom or psychopathological picture, except its transient nature and organic aetiology. It has proved to be a clinically useful concept in Germany, renewing interest in the reversible functional syndrome as a medical rather than an existential diagnostic problem. Certainly, the patient described here could retrospectively give a detailed account of his illness, indicating no clouding of consciousness, and thus representing a classical '*Durchgangs-Syndrom*'.

Ephedrine is no longer widely used as a bronchodilator, as the more specific beta$_2$ stimulants are now favoured; however, it is available without prescription and is a powerful psychostimulant. Martin *et al* (1971) compared the following drugs, administered subcutaneously under double-blind conditions: d-amphetamine, methamphetamine, ephedrine, phenmetrazine, and methylphenidate; ephedrine was found to be capable of producing the subjective and physiological effects of the other stimulants studied. Ephedrine has been marketed in the USA as 'the new legal cocaine substitute' under the name of Ma Huang Incense (Siegel, 1980). In recent years, certain 'garage laboratories' in the USA have also been manufacturing what have become known as 'look alikes'; which closely resemble amphetamine tablets in size, colour, numbering and trademark, but they contain non-controlled drugs such as ephedrine, phenylpropanolamine, and caffeine. These drugs, also known as 'pseudo-speed', are advertised quite legally in magazines and are inexpensive. Dougherty (1982) found that most of the 13 to 25-year-old drug abusers he interviewed in New York said that pseudo-speed gave them a 'rush' that was not quite as good as cocaine but sufficient to produce an adequate 'buzz', particularly when combined with alcohol; after alcohol and cannabis, pseudo-speed was the most commonly abused drug by adolescents in central New York. Young people who abuse pseudo-speed are commonly seen in emergency departments with adverse effects; e.g. one 20-year-old male was admitted one hour later with a subarachnoid haemorrhage (Wooten *et al*, 1983).

In 1965, Chapple claimed that ephedrine was being abused by young people in this country. There have been no further reports of abuse of ephedrine in the British literature, but it may nevertheless be occurring in the UK and pharmacists are aware that young people purchase ephedrine for its psychostimulant properties. In view of ephedrine's psychostimulant effects and its ability to induce paranoid psychosis, there seems to be a strong case for making it available only on prescription.

Delusion Parasitosis: Successful Non-pharmacological Treatment of a Folie-à-deux

Delusional parasitosis, originally described by Ekbom in 1938, is an illness in which the individual believes small animals such as insects, lice, vermin, or maggots are living in or thriving on his/her skin. The delusion is not secondary to another psychiatric illness, and in general the personality remains otherwise preserved. Munro (1980) classifies delusional parasitosis as a subtype of monosymptomatic hypochondriacal psychosis, and has shown that a substantial proportion of patients with MHP respond to pimozide. Prior to the introduction of that drug, the prognosis of the condition was held to be very poor.

In delusional parasitosis, *folie-à-deux* is relatively common; Skott (1978) found that 25% of her patients were involved in a *folie-à-deux*. Berrios (1985) points out that very little is known of the natural history of the illness, and suggests that the prognosis may not be as bad as is currently believed, since the evidence has generally come from the very severe and chronic cases which only come to a psychiatrist 'in extremis'. The following *folie-à-deux* of delusional infestation is reported because, as far as the author is aware, it is unique, in that remission occurred in both partners without pharmacological treatment, after only a brief period of acute psychosis.

Case report

Mr H, the dominant partner of the *folie imposée*, was a 55-year-old man, who was divorced, unemployed, and living on his own in a two-room flat. He had been referred by his general practitioner for treatment of his 'phobia', and complained that since he had laid an old carpet, 6 weeks previously, he had become infested with minuscule insects, which lived under his skin and caused intense itching and burning sensations. He had visited the Casualty and Dermatology Departments of his local hospital three times since then, with complaints of 'gritty' sensations in his eyes, and skin rashes showing 'samples' of insects for inspection. He was hurt, angry, and disbelieving when no confirmation of his infestation was forthcoming. To escape the insects, he had got rid of the carpet, had his flat fumigated, got rid of virtually all his furnishings and clothing, and finally moved to a bedsit, to no avail. He said that when outdoors, he was constantly under attack with 'black specks', which rained down on him from the air.

While firmly adhering to his view that he was infested, Mr H volunteered that he had been suffering a great deal of stress—"enough to make anyone need to see a psychiatrist". He had married at the age of 40, and this was followed 3 years, during which he exhausted himself trying unsuccessfully to obtain professional help for his wife, whom he described as irresponsible and a risk to the health of their daughter, conceived pre-maritally. Eventually, his wife left him, and took their daughter with her to the USA. Over the following 10 years, he had remained distressed and guilt-ridden about this situation. However, in 1983, 6 months after he had been made redundant from his life-long job as a clerk in a steel firm, he was informed that his ex-wife was sending his daughter to live with him. This was something he knew she did not want, and something he could not support financially; it produced great distress, and led to protracted discussions with his solicitors and with the Immigration Authorities, which were on-going at the time he developed his delusions of infestation.

His early life and development had been unremarkable, and there was no prior history of psychiatric illness; he described himself as a shy, introverted man. At interview, he talked at great length about his infestation, in an agitated fashion; apart from this delusion, there were no other abnormalities in the mental state.

Two weeks after Mr H developed this condition, his only social contact, Mr P, developed similar symptoms; he was a divorced 54-year-old man, a cardiac invalid, living a similarly isolated life to Mr H, in a flat in the same block. They had known each other for about a year, and played chess together; Mr P had continued the friendship because he felt sorry for Mr H, viewing him as a man with considerable emotional problems. Mr P said that he had begun to itch frequently, and had developed bite marks and red spots on his skin. He believed Mr H carried the insect infestation, and that close contact allowed the infestation to be transmitted temporarily to him. He had observed how bathing relieved the itching, and that his symptoms also receded when he did not see Mr H for some time; he felt Mr H had become infected because he was unhygienic. Mr P himself had presented for investigation at a dermatology clinic on two occasions; at initial assessment, the content of his speech focussed exclusively on infestation, but as much on Mr H's as his own. He was not excessively concerned about his condition, and did not press for treatment; he presented as a rather naive and suggestible man, of limited intelligence, and apart from the pre-occupation with infestation, there was no abnormality in his mental state.

Subsequently, Mr H was seen on a weekly basis over 5 weeks; a detailed history of his symptoms and life experiences was taken, and a thorough medical work-up carried out, including further assessment by a dermatologist. At no point was it suggested that Mr H was psychiatrically ill; he found this approach supportive, was appreciative of his treatment, but equally complained that he was not getting the specific help he required for the infestation. During this time, he continued his own self-help efforts to eradicate the infestation by methods such as fumigation and repeated bathing; after 5 weeks, he indicated that he felt he had finally cured himself. He described how the infestation had finally left him after two trips to the public baths, during which he had seen the insects hover around him in a white cloud, before eventually leaving him; at this point, he indicated he wished for no further interviews with the author.

Following the initial assessment, Mr P deliberately pursued a policy of avoiding contact with Mr H, and a fortnight after Mr H was cured, he indicated he was free of his symptoms. Mr H was seen a year later, in response to a request by the author; he had remained symptom-free over this time, while remaining convinced that he had been infected by some insects a year previously. At this time, Mr P was also symptom-free. Mr H now spontaneously asked for counselling and practical advice from the authors regarding his continuing distress over the family traumata, and is currently seeing the author on an infrequent basis.

Discussion

To the author's knowledge, no report of non-pharmacologically induced remission of delusional parasitosis has previously been documented. Several features may account for the favourable short-term prognosis in the case of Mr H. Firstly, the onset of his symptoms was acute, and led to a rapid involvement of potentially therapeutic agencies; many patients have been chronically deluded, sometimes for up to 20 years, before they come to the attention of psychiatrists. Secondly, and atypically, treatment could be directed both at the symptomatic and (the putative) psychological levels of Mr H's problems. He was supported in his request for medical investigation, and was encouraged to ventilate at length his distress and conflicting feelings surrounding the life experiences which he felt had distressed him over some years. Each of the therapeutic sessions was followed by a decrease in his level of distress about his emotional problems—a sense on his part that his problems were seen as important in the eyes of a significant other. Thirdly, he retained his sense of his own agency, through his own self-help measures: he maintained a belief that some measure would be effective eventually in getting rid of his infestation, and each cleansing technique generally had a short-term therapeutic effect, calming and temporarily cleansing him.

That this supportive type of approach was effective should not be totally surprising; prior to the advent of phenothiazines, undoubted cases of schizophrenia responded to supportive, non-pharmacological interventions. What is surprising is rather that no cases have been reported similar to the above: this may be because many cases go undetected, and long-term follow-up of the natural history of the condition is virtually absent. Equally, cases seen by psychiatrists are loaded towards those where organic factors such as dementia are likely to be present (Berrios, 1985).

The remission of the illness in the second partner followed separation from Mr H. The transient nature of the symptoms, their relative mildness, and their relationship to contact with the itching partner, make it likely that this illness represents an over-valued idea, rather than a primary delusional illness. The implication of this case of *folie-à-deux* is that the spectrum of illness subsumed under the label delusional parasitosis, is wider and of more variable prognosis than has heretofore been considered.

This *Journal* accepts papers from any part of the world provided they are of appropriate scientific quality. The only exception would be where there had been evidence in a paper from any country (by no means only South Africa) that unacceptable practices of political, racial, or other discrimination or abuse had been followed in the course of the work reported – *Ed.* (see Richman, N., *Journal*, 1986, **149**, 797).

Admission Rates and Lithium Therapy

SIR: Dickson & Kendell (1986) have reported their observations in Edinburgh. From 1970 to 1981, while long-term lithium therapy was increasingly employed for affective illness, the admission rates for affective disorders rose substantially. The authors find the explanation of these changes uncertain, yet they conclude that the findings cast doubt on the efficacy of lithium prophylaxis under ordinary conditions.

The question of lithium efficacy in clinical practice is very important. The authors' observations are interesting, and their discussion scholarly, but it remains unclear how their failure to explain the rise in admission rates could lead them to question the efficacy of lithium treatment in practice. As the discussion part in their paper leaves several important issues open to further questioning, connecting directly the two increases they observed appears unfounded and rather arbitrary.

The possibility of a shift in diagnostic practice may serve as one example of an unanswered question. Their data shows that while the admission rates for mania and depression rose steadily, the admission rates for schizophrenia fell. As the total number of admissions remained approximately the same, a shift in diagnostic practice would be one of the possible explanations. In many other hospitals the diagnosis of manic-depressive illness increased substantially in the 1960s and 1970s, probably because of changed therapeutic expectations (Baldessarini, 1970; Symonds & Williams, 1981). Thus, this issue is obviously critical for any conclusions about the efficacy of lithium. The authors therefore compared a sample of 20 new admissions and 20 readmissions, from both the first 3 years and the last 3 years, as to the proportion of patients fulfilling the RDS criteria for the main diagnostic categories, and they felt that these had not changed. However, this does not fully dispose of the concern; and a shift in diagnostic practice remains a strong possibility. For one thing, one would require a considerably larger patient sample to detect a statistically significant shift in diagnostic proportions. Secondly, the number of diagnosed manics has increased approximately three times, a change similar in type to the diagnostic shift described elsewhere (Baldessarini, 1970). Finally, although the data present a ten-fold increase in lithium use in Edinburgh, the authors did not find any such change in the sub-samples selected, which certainly casts doubt on how representative the sub-samples are and how relevant they are for interpretation.

In attempting to explain their findings, Dickson & Kendell had to face difficulties common to most retrospective studies. As they address an important question, one can easily identify with their predicament, as well as share their view that the explanation of the findings is uncertain. There are always major risks involved in attempting to make inferences about therapeutic efficacy from epidemiological data (Shepherd, 1961). To wit, in Hamilton, Ontario, we have observed admission changes similar to those reported by Dickson & Kendell, yet the data suggest a different interpretation. From 1970 to 1981 – a period of time identical with that of the Edinburgh study – in Hamilton Psychiatric Hospital there was a similar increase in admission rate of patients with the diagnosis of major affective disorders: from 111 to 190. This increase was paralleled by a rise in admission of these patients in all hospitals in Ontario, from 1036 to 2105 during the same time period. As in Edinburgh, the admissions of schizophrenics to Hamilton Psychiatric Hospital dropped from 520 in 1970 to 435 in 1981. The use of lithium in the area also increased dramatically, reaching in the early 1980s a rate of 2 per 1000 population; over 700 patients were on lithium in the Hamilton area, a similar figure to that in Edinburgh. Yet, despite these striking similarities with the Edinburgh trends, a cohort of 240 lithium treated patients at Hamilton Psychiatric Hospital exhibited concurrently a profound drop in expected recurrences, described in our earlier studies.

The important question of lithium efficacy in clinical practice could perhaps be approached more productively by following admissions of a clinical practice cohort of patients who actually are on lithium.

SYMONDS, R. L. & WILLIAMS, P. (1981) Lithium and the changing incidence of mania. *Psychological Medicine*, **11**, 193–196.

SIR: We agree with Schou (*Journal*, December 1986, **149**, 798–799) and Grof (above) that the findings we reported in *Psychological Medicine* last year (**16**, 521–530) do not by any means prove that prophylactic lithium therapy is ineffective, even in our own city. We ourselves emphasised that we could not exclude a number of possible explanations, including changing diagnostic criteria, for the threefold rise in the admission rate for mania that occurred between 1970 and 1981. On the other hand, we failed to find any evidence to support any of these alternative explanations. The samples of case notes we compared (40 from 1970–72 and 40 from 1979–81) yielded no hint either that diagnostic criteria had changed or that the threshold for admission had fallen between these two time periods. We are aware, of course, that diagnostic criteria for mania changed very dramatically in North America in the course of the 1970s. But Baldessarini's comments on the American scene cannot be extrapolated to Scotland. In many parts of the USA a diagnosis of mania was a rarity in the 1960s but this was never so in the UK. For example, in the comparison of admissions to mental hospitals in New York and London carried out by the US/UK Diagnostic Project in 1968 only 0.5% of the New York patients had a hospital diagnosis of mania compared with 6.9% of the London patients (Cooper *et al*, 1972). What is more, Eagles & Whalley (1985) found no significant increase in the first admission rate for mania to Scottish mental hospitals between 1969 and 1978 and it is difficult to see how any major change in Scottish criteria for a diagnosis of mania could have occurred without affecting that rate.

We do not pretend to understand why the admission rate for mania should have increased so much during a time period when the use of lithium was steadily increasing, but we are impressed by the evidence, which neither Schou nor Grof refers to, that lithium withdrawal, deliberate or inadvertent, may result in a temporarily *increased* risk of a manic episode. There are at least four reports in the literature of patients relapsing within a fortnight of their normal lithium tablets being replaced by placebo, and it is not far-fetched to suggest that patients may, for a variety of reasons, end up taking lithium intermittently more frequently under the conditions of ordinary clinical practice than in the context of a closely supervised clinical trial.

We published our findings not to deter others from putting their patients on prophylactic lithium but in the hope that they would provoke them to ask questions about mania and about lithium which they had not asked previously, and to design new studies to answer those questions. In the meantime we cannot do better than repeat the last sentence of our paper – "whatever the true explanation, there is no comfort in these findings for those, including ourselves, who have believed for the last 15 years that maintenance lithium provides an effective prophylactic treatment for at least a substantial minority of patients with recurrent affective disorders".

Panic Attacks: New Approaches to an Old Problem

SIR: Gelder's paper (*Journal*, September 1986, **149**, 346–352) should not be given more weight than it claims, as a somewhat ephemeral expression of his picture of the subject and reflecting his well-known interest in behavioural psychotherapy. However, there is the danger that some readers might mistake it for a serious appraisal of the subject, placing new ideas in relation to a review of the old ones. In particular, since the paper begins and ends with approving references to Freud, some readers might not realise the almost total omission of everything that Freud thought important on the subject. There is a case for expunging his rather dotty theories of 1895 but it seems a pity to try and understand panic attacks without any recourse whatsoever to the insights available from 90 years of psychoanalysis.

Gelder reminds us that Freud coined the term 'anxiety neurosis' in a very early (1895) paper entitled "The justification for detaching from neurasthenia a particular syndrome: the anxiety neurosis." Gelder summarises some biochemical and neurophysiological hypotheses and a theory involving hyperventilation. Turning to "psychological mechanisms", he does say that they may be equally complicated but "for the present discussion it will be enough to consider one important psychological component: the cognitive changes." This is the only hint that there might be any more to it, any more in the way of human experience relevant to the problem. In particular, there is no glimmering of what Freud's paper was about. The fact is that he was on the verge of discovering the unconscious, the interpretation of dreams and inventing psychoanalysis. In the particular paper quoted, he thought he had discovered something rather different, a theory of "actual neuroses", syndromes due to adverse sexual practices. Almost the entire paper to which Gelder refers is devoted to an exploration of the idea that "anxiety neurosis" is caused by frustrating sexual habits and by coitus interruptus in particular. He thought that neurasthenia, his other "actual neurosis", was caused especially by excessive and compulsive masturbation. These seemingly naive ideas may have made more sense in 1895 but were soon to give way to the larger insights into the workings of the unconscious that changed the shape of the planet for every literate person since. The early stumblings of a genius are fascinating to follow and Freud's *obiter dicta* had a way of getting into everyone else's language afterwards.

After all this it is rather astonishing that Gelder, asking whether the psychological component of neuroticism in panic attacks can be identified more precisely than cognitive theory permits, recalls only that "Freud (1895) stressed the anxious patient's preoccupation with fears of dying, a stroke, or loss of sanity." He adds that Beck *et al* (1974) added fears of heart disease and fainting, which sounds like an observation of almost sublime triviality – the list of expressed fears must be almost endless. Surely we could grasp Freud's point in first describing "anxiety neurosis": far from stressing the presenting symptoms, so oppressive to the patient, a psychiatrist does well to look deeper. It is a weakness of cognitive therapy that it tends to make psychology thoughtless and mindless. Of course, cognitive theory can and should take account of fantasy life and unconscious thought but too often it does not.

I find it piquant that in these very early papers Freud's approach is closer to that of the behaviour therapist than latter-day behaviour therapists seem to notice. He was then very interested in behavioural modification as a two-way interaction with thought modification and he certainly wasn't above telling people what to do. He must, after all, have been one of the astutest clinical observers and most powerful intuitive therapists ever, even though he did warn us of the dangers of *furor therapeuticum*. Furthermore, being originally a celebrated neurologist, he remained all his life deeply preoccupied with the mind–body interrelation, always wondering about the physical basis of mental processes. Perhaps we may look forward to Gelder's re-appraisal of Freud, the behaviour therapist.

Finally, Gelder gives the reference to Freud's paper as it appears in the *Collected Papers* (reprinted 1940). We probably share a sentimental attachment to those old editions but younger readers would be better referred to the Standard Edition of Freud, published jointly by the Hogarth Press and the Institute of Psychoanalysis. Strachey's translation has been criticised but remains a definitive master-work. The editorial introductions to every item are indispensable for anybody liking to place the text in its context and time.

Psychotherapy and Placebo

SIR: Michael DeMowbray (*Journal*, November 1986, **149**, 666) returns to our debate concerning psychotherapy and placebo treatment by suggesting that "the allotment of the various therapeutic factors to the categories 'specific' and 'non-specific'... is purely arbitrary and relative to the theoretical standpoint of the investigator concerned". This surely is a complete mis-statement of the position taken by psychotherapists in general. Whether they embrace the principles of psychoanalysis or gestalt, or whatever, they start with a theory concerning the origins and nature of neurosis, and derive methods of psychotherapy from these principles. It is common knowledge that these principles vary widely from one school to another, and the fact that all are equally successful (or unsuccessful) and do not do better than placebo treatment surely demonstrates once and for all that the theories involved are erroneous, and that the treatment effects are in that sense non-specific. Similarly, the fact that behaviour therapy is significantly more successful suggests that its effects are specifically derived from, and verify, the theory on which these treatments (desensitisation, flooding with response prevention, modelling, etc.) are based. All this does not relate to the theoretical standpoint of the investigator; he is simply testing the hypotheses of different psychotherapists, and assumes a neutral standpoint, as is appropriate for the research scientist.

When Smith, Glass & Miller (1980), in their book on *The Benefits of Psychotherapy,* discover, on the basis of a meta-analysis of all published studies, that there is no relationship whatever between success of therapy and duration of therapy, or between success of therapy and duration of the training of the therapist, we must surely begin to doubt the wisdom of advocating lengthy training of therapists, or lengthy treatment of patients. I have argued (Eysenck, 1980) that all psychotherapy and behaviour therapy treatments, as well as placebo treatments and spontaneous remission effects, rely on identical psychological principles, namely those underlying Pavlovian extinction of conditioned emotional responses, and that the superiority of behaviour therapy is dependent on its recognition of these principles and their explicit use in designing the treatment. The various psychotherapies, placebo treatments and spontaneous remission effects make use of these principles in a random and indiscriminate manner, and are hence less successful. Also, orthodox Freudian therapy contravenes these principles, and hence frequently harms, rather than cures, the patient (Strupp *et al,* 1977). It seems important to me that these facts should be known, and that they should be taught to budding psychiatrists. There is still an aura of successful achievement surrounding psychotherapy which is quite unjustified by all the available evidence (Rachman & Wilson, 1980). Similarly, the vast majority still spend a great deal of time being taught principles of psychotherapy which the evidence suggests are, in fact, untrue. These are serious matters, concerning the health and happiness of countless individuals, and it is important that they should not be swept under the carpet but discussed and debated on a factual basis.

Suicide in Physicians

SIR: In their paper on "Suicide in young doctors" (*Journal,* October 1986, **149,** 475–478), Richings *et al* revisit the troubling problem of the apparent vulnerability of members of the medical profession to suicide. During a sabbatical year spent in England, I used similar published and unpublished data recorded by the Office of Population Censuses and Surveys (OPCS) for 1970–72. Deaths among physicians and their wives from suicide, liver cirrhosis, accidents, poisoning, violence, and all causes combined were compared with deaths among other occupational groups (Sakinofsky, 1980*a*, 1980*b*). The standardised mortality ratio (SMR) for suicide in male physicians aged 15–64 was 335 and in those aged 65–74 was 155. Of the 15 occupational groups studied, male physicians (aged 15–64) ranked third for suicide, after male pharmacists (SMR 464) and unskilled labourers (SMR 370). Members of the political bureaucracy ranked lowest (SMR 34) after the clergy (SMR 51) and university teachers (SMR 56).

I was not able to study suicide in married female doctors owing to the peculiarity that married female physicians were at that time frequently classified by the registrars of deaths according to the occupations of their husbands! However, like Richings *et al,* I did find an excessive SMR (257) among unmarried female physicians aged 15–64 (based, however, on only 3 deaths recorded between 1970–72). Here again, far higher SMRs were recorded for female pharmacists (763 based on 3 deaths) and unskilled labourers (623 based on 18 deaths). Caution should obviously be used in interpreting SMRs based on such small numbers as are indeed also present in the data of Richings *et al.*

A further group investigated in my study was that of doctors' wives, and again I found excess mortality from suicide (SMR 458 based on 31 deaths aged 15–64) as well as from accidents, poisoning, and violence (SMR 322 based on 62 deaths). These ratios considerably exceeded those from deaths of wives of husbands with other occupations, including pharmacists (SMR from suicide 141 and from accidents, poisoning and violence 98).

It would be an oversimplification to suggest that excessive suicidal mortality in doctors and their wives is simply due to their special knowledge about lethal means as well as the ready availability of such means. However, the even greater suicidal ratio for male pharmacists clearly suggests that these must be significant factors. On the other hand, if being a doctor or a doctor's wife carries with it a special kind of distress loading, clearly the physician is not unique in this either. Being an unskilled worker may be a worse predicament. By the same token, there appear to be some professions (e.g., the clergy, politicians) that are spared excessive risks of suicide. If we are to understand why doctors and their wives are at higher risk for suicide, we might benefit from undertaking in-depth comparisons of their demographies, lifestyles and value systems with those of other occupational groups.

Mania Following Bereavement

SIR: In his letter (*Journal*, August 1986, **149**, 244) Bridges raises interesting points apart from, rather gallingly, misreading our intendedly ironic "Freudian" reference (*Journal*, April 1986, **148**, 468–70). He claims that in opposing grief and mania we create a false paradox in our patient's manic sequel to bereavement. If it is argued that grief and mania are not opposites then, by Bridges' own statements, grief and depression should have no relation. The disjunction of grief and depression is a little more problematic. The phenomenological closeness of these conditions is embedded in DSM-III, which requires the phenomena of "major depression" not to be caused by grief (p. 214). I do not believe DSM-III necessarily embodies 'truth', but it does conform to a body of respectable opinion, as do concepts of pathological grief, and to the extensive literature on bereavement and depression. Grief may be a normal experience, but it is not clearly differentiated from depression except by the presence of bereavement or loss. Bridges' placement of "happiness" as the polar opposite of grief is no less suspect than our opposition of grief and mania, or his separation of grief and depression. Only a psychiatrist who dealt with the extremes of illness would have the luxury of seeing such clear separations.

One of the worst sins of the analytic movement was to treat the hypothetical entities of "defences" as real or phenomenological entities. Bridges refers to "mani[a]-an illness" with a conviction that similarly treats the hypothetical entity of illness as a real or phenomenological entity. Moreover, psychoanalytic theory offered trite and circular 'explanations' for many mysteries of human behaviour and thereby closed them to investigation for decades. To speak of "specific vulnerability/non-specific stress' creates an illusion of explanation which threatens to do the same.

The Prognosis of Depression in Old Age

SIR: Baldwin & Jolley (*Journal*, November 1986, **149**, 574–583) point out that "much thought needs to be given to research methodology in this field." I could not agree more; the authors' retrospective study of case notes can hardly be regarded as rigorous or comparable with a prospective follow-up study of the type I conducted. It is well recognised that case note reports of outcome frequently bear no relation at all to the mental states discovered in face-to-face interviews and no doubt the same vagaries of reporting afflict doctors' notes in Manchester as they do in East London. Baldwin & Jolley did, however, interview those alive for their long-term study. They reported a mortality rate (35%) remarkably similar to the 37% mortality rate of the East London cohort over a 4 year period (in press). If the dead are excluded, then 40% of their patients remaining alive were either 'continuously ill" or suffering from "depressive invalidism". No different from Post's findings and not much different from mine!

It seems to me that where our methodology is similar, the results are similar, though perhaps they view the same results with more optimism. Baldwin & Jolley's pint pots are always half-full, whereas mine are half-empty!

Depression in School Phobia

SIR: We note with concern the comments of Weinberg *et al* (*Journal*, March 1986, **148**, 335). Some of the phraseology suggests that their views may be influenced by considerations beyond the substance of the Newcastle method. They enunciate standards which are easier to apply to the work of others and also over-emphasise shortcomings which we have already listed. In the selection of diagnostic criteria, we had pointed out (p. 353) that, as there was no control group (normal controls), the items identified would not necessarily discriminate between those who were well and those who were depressed.

As to his other points: (i) We believe it is valid to attempt to distinguish between neurotic disorders in childhood with and without depression, but have stated that further work needs to be undertaken to establish whether our formula can be applied more widely. Recent research on a fresh population has validated the formula. (ii) Reliability has been previously reported (p. 355 and Berney *et al* (1981). (iii) We are aware of the evidence for a genetic basis for bipolar affective disorder, but the case for this is less strong in the milder depressive disorders which present in out-patient practice. (iv) The theory of an underlying substrate of right cerebral dysfunction is controversial and cannot be supported as yet.

We regret the confusion about the origin of the Weinberg criteria, which derive from the Washington University research criteria. However, other workers (Puig-Antich, 1980) have already pointed to serious methodological flaws in the use of these criteria by Weinberg. By RDC criteria we imply the variation used by Puig-Antich. The current Newcastle Depression Project has looked again at the various sets of diagnostic criteria in relation to a clinic population (Kolvin *et al* – in preparation).

We also note with interest the comments by Atkinson (*Journal,* March 1986, **148,** 335–336). There are some major as well as some simple misunderstandings of the procedures used. We disagree with some of the views expressed. He also seeks extensive statistical details which are not usually published.

Comparison of groups (Table I). It is axiomatic that statistical critics should get their formulae right. On Atkinson's own analysis, a 31-item total global depressive score would lead to a probability of 1.5 and there is no such thing! Further, the formula would need to be modified when using higher levels of significance.

Initially our data in Table I was presented both as percentages and as means and standard deviations. Subsequently we used the device of the best cut merely for the ease of presentation. We agree that in the comparison of the groups it would have been best for us to make a cut on *a priori* theoretical grounds. The above use of the term 'best cut' when comparing groups has given rise to confusion.

Best cut approach. We agree this is best confined to the technical sense of identifying the optimum point for discrimination on a scale used for screening purposes. We merely revised the threshold of the cut so as to identify the optimum point for the purpose of discriminating cases from non-cases. Making a cut on *a priori* theoretical grounds does not allow the emergence of the most sensitive discrimination. This is a legitimate technique and does not inflate the discriminant efficacy of the measures in question.

Item analysis. The ideal sample would have included children matched for age and sex from the general population, but this was not feasible.

Use of weights derived from discriminant function analysis. Discriminant function analysis was used to explore a series of hypothesised classifications. Data from our multivariate analyses did not contribute to our diagnostic formula. We have not used weights derived from discriminant function analyses. This is a laborious technique which offers no clear advantages over simpler methods (Goldberg, 1972).

Principal component analysis. (i) This is a robust technique well suited to clinical data which may not fit classical assumptions of multi-normality. Atkinson cites a ratio (of subjects to variables) of 5 : 1, but others recommend a ratio of not less than three or four times as many observations as variables (Taylor, 1977). It is true that we interpreted this rather liberally in relation to social and family background data, but we were cautious in the conclusions we drew. While in PCA the ideal sample size should be relatively large, we again contend that it can be used as an exploratory tool on a moderately sized sample. Dogmatic statements about sample size suggest an inflexibility in the use of statistics. (ii) In the first PCA the correlation matrix was only moderately consistent with an underlying structure and our criterion for determining the number of components was that of a variance which stood out as far larger than the rest. This is a pragmatic and arbitrary approach but more sophisticated techniques are inappropriate in a small sample (Lawley & Maxwell, 1971). In the second PCA the correlation matrix proved more consistent with an underlying structure and the first two components accounted for a substantial amount of the variance. A retrospective analysis, using the rule whereby the number of factors extracted is equal to the number of Eigen values greater than unity, supported our decision. We did not use rotation because the '*n*' was moderate. While some of the factor loadings which were noted were rather low, this does not detract from the differentiating bipolar second component which contrasts affective symptomatology with premorbid personality traits.

As clinical investigators we have presented the early steps in the development of a set of diagnostic criteria – fully aware of the pitfalls of our method. We were equally aware both of the importance of using scarce opportunities to their full, and of the necessity to ensure further validation and replication on fresh samples.

Psychiatric Morbidity and the Mentally Handicapped

SIR: Day (*Journal*, December 1985, **147**, 660–667) reported that 30% of mentally handicapped residents aged over 40 years and 20% of those admitted to a psychiatric day hospital for the mentally handicapped aged over 40 years had a significant psychiatric disorder. This study contains artefacts which lead to an over-estimation of the prevalence of psychiatric disorder.

No information is given concerning reliability. Poor reliability may have occurred at the time of diagnosis, during transcription of diagnoses from case notes, when diagnoses were re-classified into five super-ordinate categories (e.g., into the categories "psychosis" vs "psychosis"), and when diagnoses were made from case notes only (as in 6% of cases).

If the aim of the study was to estimate the current prevalence of psychiatric disorder then the inclusion of people with a history of psychiatric disorder clearly inflates this. For example, people may have previously suffered a single episode of an illness or may have been treated and no longer show the disorder.

Day gives no formal definition of "behaviour disorders" although he refers to examples of this. Whilst some instances of such behaviours have been shown to be associated with specific disorders (e.g., Lesch-Nyhan syndrome) it is not clear what *proportion* of such behaviours are indicative of psychiatric morbidity. Some behaviour disorders are associated with painful physical illness such as otitis media, undetected dental abscesses and chronic nasal infection. Others may be considered examples of learned behaviours. Behaviour disorders are clearly of heterogeneous origins and only some are psychiatric in nature (Jacobsen, 1982).

Finally, Day includes a number of offensive and troublesome behaviours as psychiatric morbidity. These include behaviours such as wandering, stealing, and public masturbation. Such problems may not reflect psychiatric morbidity in all cases but a variety of other problems such as lack of privacy, poor learning history or an environment which maintains aberrant behaviours.

Behaviour disorder accounted for 50.5% of psychiatric disorders in the long-stay residents and 35.5% of the day hospital admissions. If a substantial proportion of these could not be demonstrated to be psychiatric in nature then the prevalence of psychiatric morbidity would fall substantially.

The Effect of Sulpiride on Negative Symptoms of Schizophrenia

SIR: Activating or disinhibitory effects of neuroleptics given in low doses to patients with schizophrenia were described when these drugs were first introduced to psychiatry (Delay *et al*, 1957), but subsequent experience with conventional anti-psychotic drugs has failed to provide convincing evidence of a useful dose-related bipolarity of effect. From the time of its original use in psychiatry, however, subsidiary effects of sulpiride – described in a variety of terms such as "anti-autistic" or "thymo-analeptic" have repeatedly been noted (Collard, 1969), and neuropharmacological studies (Sokoloff *et al*, 1980; Brown & Arbuthnott, 1983) suggest sulpiride may show a clinically useful separation of dose-related effects on psychiatric symptoms, low doses having activating and/or antidepressant properties, while higher doses are effective against positive symptoms of schizophrenia.

Since there are no controlled studies in this area, we have undertaken a double-blind comparison of normal versus low dose sulpiride in patients with chronic schizophrenia characterised predominantly by the negative symptoms poverty of speech and flattening of affect.

Six women and 11 men, aged 18 to 35 (mean = 27), with a diagnosis of schizophrenia according to Feighner's diagnostic criteria for 2 to 12 (mean = 7) years, and complying with Wing's 1961 criteria for negative symptoms, were randomly allocated on a double-blind basis to treatment with sulpiride at a dose of either 50 mg ($n=9$) or 400 mg ($n=8$) three times daily. All patients completed 30 days, and 12 (low dose $n=7$, normal dose $n=5$) completed 60 days of treatment.

Brief Psychiatric Rating Scale (BPRS) and Clinical Global Impression (CGI) scores were obtained at standard intervals during the course of the study, and the patients were examined daily for side-effects. Prior to the study, two patients had never had drug treatment, and the remainder had received no drugs for a mean of 82 days (range 7–540).

Only the low dose patients underwent significant improvements, both clinically and statistically. At 30, 45, and 60 days the BPRS mean total had decreased significantly from the Day 1 value, and analysis of symptom scores showed this improvement was due mainly to a fall in the portion of the total score contributed by the items 'emotional withdrawal' and 'blunted affect', i.e. the negative symptoms. After 30 days' treatment, mean 1200 mg versus 150 mg dose negative symptoms sub-totals were 10.5 vs 7.7 (Day 1 scores 10.8 vs 9.7), t-test (2-tailed) between changes of each score from Day 1 significant at $P<0.01$; after 60 days, 10.0 vs 2.7, $P<0.01$. The CGI, which would have been largely determined by the predominantly negative symptom profile of each patient, showed a similar result of significant improvement from Day 30 onwards restricted to the low dosage group. Two patients on normal dosage experienced an episode of acute dystonia at the start of treatment, which resolved spontaneously; there were no other significant side-effects.

Full details of the study are being submitted for publication. However, in recent years, particularly as a result of the work of Johnstone *et al* (1978) on the isomers of flupenthixol, it has been considered increasingly likely that the beneficial effects of conventional neuroleptics are restricted to positive symptoms (delusions, hallucinations, and thought disorder) of schizophrenia, and we think this result with an atypical anti-psychotic drug is of interest.

Allergic Type Response to Trazodone

SIR: Trazodone is a triazole pyridine derivative unrelated in structure and pharmacology to the tricyclics, tetracyclics and monoamine oxidase inhibitors. It has been associated with dermatological reactions including erythema multiforme (Ford & Jenike, 1985) and leukocytoclastic vasculitis (Mann *et al*, 1984). We wish to report what appears to be a previously undescribed reaction.

Case report: C.M. is a 52-year-old male executive with a history of myocardial infarction in 1972 and 1983. He underwent triple bypass surgery in 1984 and has been physically well since. Six weeks prior to presentation he was involved in a minor road traffic accident with no physical injuries. He began to complain of persistent anxiety, marked insomnia, loss of confidence, lethargy, social withdrawal, irritability, loss of interest in his job, and consistent depression with diurnal variation. He had no previous personal or family history of psychiatric disorder. A diagnosis was made of a depressive anxiety state precipitated by a traumatic episode. In view of his cardiac status he was commenced on trazodone (50 mg t.i.d.). He was on no other medication. Within 24 hours he noted swelling of the index finger of his right hand and within a further 24 hours both his hands became markedly swollen to the extent of his being unable to make a fist. He reported this to the local casualty officer but neglected to mention that he was on medication. Observation was advised and no medication was prescribed. He continued to take trazodone and within a further 24 hours both his feet and legs developed significant swelling. He also complained of a generalised throbbing headache. At this stage he discontinued the trazodone and his symptoms totally resolved over the next 48 hours. He reported this condition on follow-up. In view of his cardiac condition he was not challenged again with trazodone.

This pattern of clinical presentation and resolution with cessation of the drug indicates that the symptoms were directly related and is suggestive of an allergic type response.

We wish to thank Roussel Laboratories for their kind help and co-operation with this report.

Obsessive-Compulsive Disorder – A Complication of Benzodiazepine Withdrawal

SIR: There has been increased awareness in recent years of the symptoms of benzodiazepine withdrawal. Although obsessional symptoms have been described as part of this withdrawal syndrome (Ashton, 1984), obsessive-compulsive disorder (American Psychiatric Association, 1980) has not previously been reported.

Case Report: The patient, a 32-year-old married woman, had a history of recurrent depression treated by diazepam (6 mg daily) for the previous 7 years. She discontinued this abruptly in June 1985 on her general practitioner's advice as she was planning a pregnancy. Two weeks after discontinuing medication she developed symptoms of anxiety, insomnia, nightmares, and hyperacusis, similar to those reported by Tyrer *et al* (1983), which persisted for several weeks. Four weeks after discontinuing diazepam, however, she also developed obsessive-compulsive symptoms related to a fear that she might inadvertently reveal information to other people which would lead to the loss of her home and family. This resulted in her hoarding rubbish and avoiding going out alone. When outside her home she would stop and collect any rubbish on the road or pavement. She repeatedly checked the contents of her dustbin and also her own and other people's clothes, shoes, pockets, and money. She frequently asked her family for reassurance and help with her checking rituals. She refused to be left alone in the house for fear that she might throw "evidence" out of the window and, ultimately, required a family member to accompany her to the toilet or bath. During the night she would wake her husband and request him to go into the garden to check that she had not thrown anything out of the window. Her symptoms temporarily abated when in September 1965 she recommenced diazepam for a 2-week period, but they returned and increased in intensity on its cessation. In December 1985 she developed a severe depressive illness and was admitted to hospital in February 1986 following her general practitioner's request for a psychiatric opinion. As an in-patient she was treated with clomipramine (150 mg daily) and after 4 weeks was free of depressive symptoms. However, her obsessive-compulsive symptoms remained until April 1986 when a treatment programme of graded exposure in real life with self-imposed response-prevention (Marks *et al*, 1975) was instituted. In July she was discharged from active behavioural treatment with marked improvement in her obsessive-compulsive symptoms. She has continued to improve with homework practice and at follow-up in September 1986 was able to perform home-management tasks with little fear, although remaining anxious when walking along outside her home.

As well as suggesting a previously unreported psychiatric complication of benzodiazepine withdrawal, this case demonstrates that when depression coexists with obsessive-compulsive disorder, treatment of the depressive symptoms may not lead to resolution of the obsessional symptoms (Marks *et al*, 1980).

Schizophrenia and Ethnicity

SIR: The frank suggestion by Teggin *et al* (*Journal*, November 1986, **149**, 667–668) that South African Xhosa patients are members of the Third World whilst their White compatriots live in the First World is to be welcomed. Nevertheless, it seems somewhat disingenuous to take as instances of "scientific truth" social and psychological variables which are dependent upon a system of racial classification which for many years has had no scientific support from social scientists or physical anthropologists. "Ethnicity" is a complex and polyphemous notion; to use it unproblematically, however, as if the psychiatric characteristics of a particular group can be understood in independence of a political system of classification and social control, is extraordinary.

Relationship of Mood Alterations to Bingeing Behaviour in Bulimia

SIR: In their study of 12 patients with bulimia, Kaye *et al* (*Journal*, October 1986, **149**, 479–485) have presented an example of the use of paradox in treatment. Subjects were first told they were entering hospital for a study rather than for treatment. They listed their favourite binge foods before admission and every effort was made to obtain these. They were given a private room and encouraged to take as much time as they needed to achieve the "desired effect" of their binge and vomit, having been supplied with a tray of 5000–6000 Kcal of food for the purpose. This was followed by the attentions of a physician as soon as the binge and vomiting was completed to the subjects' satisfaction. It would be interesting to know whether such a programme had any effect on the subjects' bingeing and vomiting behaviour. Could this be a model for a novel treatment approach?

Is There a Lithium Withdrawal Syndrome?

SIR: The paper by Mander (*Journal*, October 1986, **149**, 498–501) contains problems and an attractive enigma. The author used the words "withdrawal" and "relapse" interchangeably: they are not so. In any chronic condition, whether on or off treatment, in a stable state, making any change to that regimen (e.g. stopping lithium) is likely to effect a reaction (e.g. a relapse). The author proves this point. The pursuit of the question as to whether there is a withdrawal effect on stopping lithium that increases the number of relapses in the early stages can only be shown if there is a fall in the relapse rate lower than expected for a period after the withdrawal syndrome has ended. However, the theoretical relapse rate can never be known since the withdrawal syndrome "shadows" it. How can one distinguish a withdrawal state causing relapse and relapse alone?

CORRIGENDA

Journal, October 1986, **149**, 471–474 (P. Thompson). In Table I (page 472) the number of patients with 4–9 seclusions in 1984 should be 7 and not 1.

Journal, November 1986, **149**, 592–602 (W. A. Arrindell & P. M. G. Emmelkamp). The second sentence of the fourth paragraph of the 'Results' section (page 598) should read as follows: "On neuroticism, the partners scored as high as partners of other patients and as high as maritally non-distressed males, and significantly lower than maritally distressed males ($P < 0.0001$), who as a group had the highest mean score (Table I)". The first sentence of the 'Sexual maladjustment and sexual dissatisfaction' section (page 598) should read "Agoraphobics were found to rate their sexual relationships with their marital partners as less adjusted than maritally non-distressed females did, but as significantly more adjusted than those of female non-phobic psychiatric subjects, and as 'adjusted' as the sexual relationships of maritally distressed female subjects".

Journal, November 1986, **149**, 631–635 (R. Noyes *et al*). The following should be added to the penultimate paragraph (page 634): "Anxious patients often report unsatisfactory interaction with physicians and alienation from them as well (Clancy & Noyes, 1976). In fact, their hypochondriacal attitudes and behaviour can seriously disrupt the doctor–patient relationship, resulting in unsatisfactory treatment (Pilowsky, 1980)."

Book Reviews

Editor: Sidney Crown

Psychotherapeutic Intervention in Hysterical Disorders. By WILLIAM J. MUELLER and ALBERT S. ANISKIEWICZ. Northvale: Jason Aronson. 1986. Pp. 300. $30.00.

The authors are Professors of Psychiatry at Michigan State University who practise counselling psychology. Their book is devoted to the intensive psychodynamic treatment of their female clients with hysterical personality disorders.

They state simply that male hysterical personalities are the subject of extensive treatises in their own right. They aim to deal with the processes of psychotherapy in this field, for the benefit of a broad range of mental health personnel, and regard the client/patient distinction as semantic and not substantive. Their chapters work through this topic steadily and clearly.

Within the limits which they set themselves, they do an excellent job. It is not quite what their title implies, since actual conversion and dissociative disorders are totally ignored. Indeed, at the outset they identify hysteria, which is notoriously old, with hysterical personality, which so far as its description is concerned is a twentieth century concept. They also provide no systematic evidence for their ideas except for recurring vignettes of various transactions with patients which illustrate their theme. Reference is made to other work in which they have diagnostic and follow-up data on a large number of female hysterics, but this is not quoted in any detail nor is it described. Thus, the reader will be disappointed if he seeks organised factual data from which arguments can be adduced or refuted. He will have to accept or reject their statement that "... the determinants of the hysterical personality can be recast as a series of six critical developmental stages: (1) unseating the mother, (2) the mother's resignation, (3) the father-daughter pact, (4) the unmasking of the father when the daughter reaches puberty, (5) the mother's collusion in rebinding the daughter, and (6) the daughter's attempts to renegotiate a relationship with her parents".

These ideas are presented in a clear, sensitive manner which is sympathetic to the patient (client) and realistic about management, transference, and countertransference. It is not scientific psychiatry but it is instructive and gives valuable anecdotal material about what happens in interviews with many patients – perhaps not only with those who conform to the stereotype of the hysterical personality. Anyone learning psychotherapy or polishing his established skills could well benefit from some of the authors' descriptions of their dealings with their clients.

In the literature today the concept of the hysterical personality is intriguing and quite well defined. Many assumptions are held about it on the basis of psychoanalytical theories which lack solid evidence. To provide good data for or against such assumptions is a task which receives little attention, although Lazare and his colleagues made a start in work which was published as long ago as 1970. The present volume is a useful description of what is believed rather than of what can be said to be known.

HAROLD MERSKEY, *Professor of Psychiatry,*
London Psychiatric Hospital, Ontario, Canada

Bereavement: Studies of Grief in Adult Life (2nd edition). By COLIN MURRAY PARKES. London: Tavistock. 1986. Pp. 265. £12.00.

The first edition of *Bereavement*, published in 1972, was rightly acclaimed as a landmark; the second edition is no less valuable, particularly because it introduces the reader to some significant research findings which have accumulated in the intervening years. Understandably, Dr Parkes' review of the research literature is selective, but he is generous in his reference to more extended reviews.

The content and the easy literary style will make the book attractive to a wide readership, including researchers, teachers, clinicians and the bereaved. Theoretical concepts and practical principles are comfortably interwoven, and the reader is shielded from an excess of detailed research data by the fact that the latter have been presented separately in an Appendix. In the main text there are good descriptions of various features and forms of grief, including that which follows other kinds of loss, e.g. amputation. In his descriptions Dr Parkes does not stray from his most valuable source of information and insights – the bereaved – and, thus, his descriptions are punctuated with illuminating quotations and references to real people and incidents. Fortunately, however, he avoids generating the kind of mulch of sentimental anecdotes which some authors in this field provide for us.

Of particular practical relevance are the chapter devoted to helping the bereaved and the list of organisations concerned with such help.

This is a commendable book. It is to be hoped, however, that the sense of understanding which readers will derive from Dr Parkes' generalisations does not blunt their sensitivity to individual differences. The author's own comment should be borne in mind: '.... every person and every grief is different...'. (P154).

D. A. ALEXANDER, *Senior Lecturer in Mental Health, Medical School, University of Aberdeen*

AIDS: A Plague in Us. A Social Perspective. By ANTHONY A. VASS. Huntingdon: Venus Academica. 1986. Pp. 177. £7.95.

Dr Vass's book provides a stimulating account, not of the medical, but of the social, impact of AIDS for the individual and society. As a sociological analysis it is an important contribution both for the policy maker and the general reader.

The book draws on international sources but focuses on data from the UK. The first chapter documents the role of the media in the 'making of a panic' and the subsequent individual, government and policy response to the 'crisis' of the AIDS epidemic.

The second chapter reports on a small survey of laypersons' and social workers' opinions. Personal fear of contagion in the face of the unknown, the public call for information and victimising responses to members of high-risk groups are the predominant themes emerging from this work.

An account of the medical response draws attention to the immense research efforts, but not without valid criticism of the contribution of the medical profession to the premature presentation of research findings, and of frank conjecture in the presentation of 'facts' about the epidemic.

The book is as up to date as any can be on such a fast-moving subject. It provides an important analysis of society's response to a problem whose ultimate size we cannot predict. In some places the material is repetitive and its diversity occasionally makes it difficult to follow a clear thread in the development of the sociological analysis. By his own admission, the author raises as many questions as he answers. Of course, for the individual clinician there are no simple solutions for clinical management; for the Public Health Doctor there are no answers for epidemic control but there are plenty of lessons in the pitfalls to avoid.

The reader is forced to face the tightrope which we walk in making a humanitarian response to a social problem, which is ultimately everybody's, and which we seek to control. We do not yet know if this can be achieved without creating the reactionary and punitive measures of the plagues of old.

In Dr Vass's concluding words, the answer 'lies in the way in which we can manage our strained social relationships and come out of them fairly intact and safe as a society'. We would do well to heed his warning.

ANNE M. JOHNSON, *Lecturer in Genito-Urinary Medicine, Middlesex Hospital Medical School, London*

Essential Papers on Object Relations. Edited by PETER BUCKLEY. New York: New York University Press. 1986. Pp. 477. US $50.00 (hb), $22.50 (pb).

This book is one in a series entitled "Essential Papers in Psychoanalysis", the other titles in the series being on Borderline Disorders, Narcissism, and Depression. After an introduction, the book is divided into three parts. The first part is entitled 'Instincts Versus Relationships: The Emergence of Two Opposing Theories' and starts with part of Freud's three essays on the 'Theory of Sexuality' and follows with Melanie Klein's paper on 'The Psychogenesis of Manic-Depressive States' and further papers by Fairbain and Arlow.

The second part is entitled 'Object Relations and the Development of the Child' and contains classical papers by Bowlby, Mahler, and Winnicott, including his paper on 'Transitional Objects'. There is also a paper by the Sandlers 'On the Development of Object Relationships and Affects'. The final part is entitled 'Object Relations, Psychopathology and the Clinical Situation'. It contains an interesting paper by Annie Reich on 'Narcissistic Object Choice in Women', a paper by Edith Jacobson on depression, one by Modell on 'Primitive Object Relationships in Schizophrenia' and an article summarising Kernberg's views. Finally, there are papers by Loewald, mainly on his classic 'The Ailment' and Guntrip's personal experience of analysis. It would have been nice if each paper had a date with the title so it could easily be seen in its historical context.

Despite the quality of the papers, I was left questioning the purpose of the anthology. Most of the papers are familiar already to anyone involved in the psychoanalytic field, a substantial number being accessible in the journals. Also, with such an enormous topic it is not possible to cover the whole field and any collection must be, to some extent, the individual's choice. There seems to be an overlap with the other books in the series, in the sense that there are articles here on narcissism, borderline states and depression. If the intention of this book is to highlight the development in understanding of particular types of object relations, I would like to have seen included a paper on Bion's concept of the "bizarre object" in psychosis, and also more on the place of symbol formation.

Despite these reservations, the anthology might prove useful in terms of a basis for reading seminars for psychiatrists and related workers, as part of an overall psychotherapy teaching programme. It would be important that the papers are evaluated in relationship to one's clinical experience, to get the most out of them.

RICHARD LUCAS, *Consultant Psychiatrist, Claybury Hospital, Essex*

Mental Deficiency: The Changing Outlook (4th edition). Edited by ANN M. CLARKE, ALAN D. B. CLARKE and JOSEPH M. BERG. London: Methuen. 1985. Pp. 834. £40.00.

This is the 4th edition of a book that has played a major part in the education of many professionals who work with people with a mental handicap. The reading of the 4 prefaces, the first written in 1958 and all included in this book, gives the historical perspective written as services were developing which is far more powerful than any retrospective account of such a series of changes. Throughout the book there has been a determined effort to use modern terminology for the inevitable process of labelling but the book itself is still called "Mental Deficiency", which will surprise many but is debated and defended by those responsible for its retention.

The book has both a multidisciplinary and a multinational authorship with the various chapters displaying a remarkably even standard of approach and complexity. All embody a review of the literature and reflect the need to value the truly scientific approach to the increasingly complex issues surrounding the understanding and management of a person with a mental handicap.

There continues to be an emphasis on the biomedical, the biosocial and educational aspects with much of the book devoted to aetiology and prevention in its widest context. Therapists will be interested in the chapter on "Microelectronics and Computer-Based Technology", and nowhere is the gap seen more clearly between research and practice than in the chapter on "Communication".

In most of the chapters the sophistication of the knowledge base as portrayed demands a commitment and careful study by the reader and this is not a book to browse through in an odd moment. It is hard to find anything missed out from this book, but perhaps more attention will be paid to the carers' needs for support and the risk of "burn out" in a subsequent edition, on which I suspect and hope that work has begun already.

JOAN BICKNELL, *Professor of the Psychiatry of Mental Handicap, St George's Hospital Medical School, London*

Chemotherapy in Psychiatry: Principles and Practice (revised and enlarged edition). By ROSS J. BALDESSARINI. London: Harvard University Press. 1986. Pp. 354. £21.25.

Most of those commencing their training in psychiatry are on the look-out for a comprehensive, informative and readily accessible textbook concerning the use of drugs in psychiatry. Unfortunately, although this book contains much useful advice the information is not easy to extract and I would not feel that it is a book I would recommend to trainees.

The first chapter provides an historical context for modern psychopharmacology with a description of drug development in the pharmaceutical industry. The second chapter on antipsychotic agents has an overall three-part layout: pharmacology, clinical use, and toxicology. This pattern is repeated in the three following chapters which cover lithium salts and anti-manic agents, antidepressant agents, and anti-anxiety drugs respectively.

The chapter on antipsychotic agents covers the short and long-term use of such drugs and contains much useful information, but at times this proves hard to extract from the prose. The following chapter on anti-manic agents provides a comprehensive review of the advantages and disadvantages of lithium therapy but relegates the use of carbamazepine to a paragraph in the section on 'alternative and experimental treatments'. The chapter on antidepressant agents reaches a mammoth length of 104 pages, in contrast to the 34 pages on anti-anxiety drugs. Despite mention being made in both these chapters of the use of antidepressants in panic disorder, no clear guidelines are given. All these chapters mention research investigations but no methodological detail is provided, making critical assessment problematic for the reader, although a good reference list is provided. The final chapter covers 'special topics' which includes useful notes on geriatric and paediatric prescribing as well as a discussion of clinical and medical responsibility.

It is to the author's credit that despite this being an American text mention is made of drugs used in Europe but not in the USA. The absence of mention of what approach to take towards alcohol withdrawal or of the recent work on the placebo response reduces the usefulness of the text to trainees in psychiatry. Although the book has good aspects it cannot be considered a comprehensive text. It aims to be a practical guide but repetition and the inaccessibility of the information mitigate against its use in teaching and clinical practice.

ANNA HIGGITT, *Research Worker,*
Institute of Psychiatry, London

Paradoxical Strategies in Psychotherapy. A Comprehensive Overview and Guidebook. By LEON F. SELTZER. Bognor Regis: John Wiley. 1986. Pp. 323. £31.75.

If I write "Readers of this *Journal* will not be interested in this book because American psychotherapy texts are always sloppily written and unscientific" with the thought in mind that this will irritate readers sufficiently that they will want to read the book, then I have used a paradoxical strategy. Such strategies are particularly employed by family therapists who make use of systems theory. Phrases like "symptom prescription" and "relapse prediction" connote some of the techniques which have been described, particularly by workers at the Milan Centre for Family Studies since 1971.

However, in this well written and scientific book Dr Seltzer takes a broader view of the paradoxical element in psychotherapy. He draws in ideas from Freud, Adler, and others in the psychoanalytic tradition, techniques used in the behavioural therapies such as "massed practice" and "paradoxical intention", and important elements of gestalt therapy such as "staying with" unwanted thoughts and feelings. This discussion of links between techniques allied to disparate theoretical approaches highlights the value of utilising positively the patient's reluctance to change and of promoting conscious control of habitual, unwanted behaviours.

The sections on empirical research remind us how insubstantial are research results in psychotherapy generally and give the critical reader a sense of proportion in evaluating the theoretical contributions. There is a useful set of appendices which includes a selection of papers on the planning and execution of paradoxical strategies and a comprehensive bibliography.

This book should appeal to a wide variety of readers interested in psychotherapy theory, research or practice.

ERIC CROUCH, *Consultant Psychiatrist,*
St John's Hospital, Aylesbury

Health Needs of Women as they Age. Edited by SHARON GOLUB and RITA J. FREEDMAN. New York: The Haworth Press. 1985. Pp. 122. $24.95 (hb). $19.95 (pb).

I looked forward to reading this book about a topic of great importance but about which I felt ignorant. By the end of the century, the number of people aged 75 and over in this country is expected to increase by about one-fifth and the number aged 85 and over by no less than one half. Elderly women will outnumber elderly men considerably.

Most care of the elderly is undertaken in the community – much of it by women. Because of a lower birth rate, there is now a lower ratio of carers to those in need. Furthermore, many more women are now working, so are less free to look after their elderly relatives.

Unfortunately, this North American book was a great disappointment. It was parochial and rather boring. A number of topics were covered so superficially that it was not worth bothering. Some chapters did not even address issues related to elderly women.

After an introductory overview, there were chapters on social policy, long-term nursing, respite care, Alzheimer's disease, reproductive cancer, hypertension, eye problems, osteoporosis, and psychological aspects. It was not clear who the book was for and it provided little practical information that would be of use to clinicians, be they general practitioners or psychiatrists. Important omissions were health promotion, prescribing, nutrition, and arthritis. There are many better British books on the market dealing with the health needs of the elderly, and covering the special needs of women as well as men.

PETER ANDERSON, *General Practitioner and*
Senior Registrar in Community Medicine,
Community Health Offices, Oxford

Growing Points of Attachment Theory and Research. Edited by INGE BRETHERTON and EVERETT WATERS. Chicago: University of Chicago Press. 1986. Pp. 320. $14.50.

This monograph of the Society for Research in Child Development would be of prime interest to developmental psychologists, but could be useful also to child psychiatrists, particularly at the basic trainee stage. A collection of papers, mainly by experimental psychologists, it aims to review the work on attachment by Bowlby, Ainsworth, and others, and bring it up to date, drawing upon recent research material.

The book is divided into four parts of which Part 1, called "Introduction", is an overview of attachment theory in retrospect and prospect by Inge Bretherton. For those with limited reading time this would be the most useful chapter to read, as it highlights the important issues and refers forward briefly to some of the research data published later in the book. Part 2 deals with theory and current methods of assessment and there is a lot of detailed research material, including a description of a Q-sort method of assessing attachment security. The third part consists of six separate papers studying attachment in different situations, e.g. in institutionally reared infants, "high-risk" infants, or maltreated infants. The final part makes an attempt at cross-national study and includes three chapters presenting attachment research findings in North Germany, Kibbutz-reared Israeli children, and in Japan. In picking out just three countries it cannot, of course, be a comprehensive review, but it does pinpoint significant differences which could be attributed to differing attitudes to child-rearing.

Each chapter is by a different team of researchers and could be read separately. In fact, I would not recommend attempting to read the book through from cover to cover as this would inevitably seem repetitious; for example, most of the research studies make use of Ainsworth's "Strange Situation" experimental technique for assessment of attachment patterns.

PATRICIA AINSWORTH, *Lecturer in Child and Adolescent Psychiatry, University of Manchester*

Autistic Children: New Hope for a Cure. Edited by N. TINBERGEN and E. A. TINBERGEN. London: George Allen & Unwin. Pp. 362. £9.95.

The authors, distinguished ethologists, have used their skills as expert observers of animal behaviour to study autistic children. On the basis of their observations they conclude, in disagreement with the prevailing expert opinion, that the autistic condition is in essence an emotional or motivational disturbance, a state of anxiety-dominated inbalance which impairs the child's ability to interact with the environment. The various perceptual, cognitive, motor, and speech deficits are regarded as peripheral and secondary to the central emotional impairment. The basic problem would be brought about by early traumatic experiences in infancy, i.e. a difficult delivery, separations from parents, moving houses, the birth of a sib. The authors believe that many mothers manage to coax their autistic child back to normality, if top priority is given to the reduction of the child's abnormal feelings of insecurity and of the mother's inability to cope emotionally with her child. They particularly favour the technique of holding the child for prolonged periods in order to reduce distress and to facilitate the development of normal social responses.

Unfortunately, though their case may appear compelling, it is by no means proven. There is no attempt by the authors at testing their views with a controlled design, and insufficient consideration given to opposing evidence available from other sources. While some of the cases histories given in the book emphasise the fact that some children with marked autistic features can improve substantially, and the ability of some parents to respond extremely competently to them, this cannot be taken as conclusive evidence to support the authors' theories or their general optimism about outcome. Regrettably, this optimism could give false hopes to distressed parents. This is a disappointing book.

ELENA GARRALDA, *Senior Lecturer, Booth Hall Children's Hospital, Manchester*

Rehabilitation in Psychiatry: An Introductory Handbook. By CLEPHANE HUME and IAN PULLEN. Edinburgh: Churchill Livingstone. 1986. Pp. 230. £8.95.

This introductory handbook succeeds in its aim to acquaint the novice of whatever professional discipline with the scope of psychiatric rehabilitation, by providing readable basic information. It includes brief critical reviews of the history of institutions and of some of the notable literature on institutionalism and on community treatment. The sections on the nature of disability and the principles underlying rehabilitation are perhaps too short, but the right emphasis is placed on the practical aspects of assessment, planning, and service organisation, as well as on the importance of long-term (often life-long) commitment to chronic patients in the community. Working with families both as units and in groups is given due prominence. The book is particularly good on the organisational aspects of a rehabilitation service, including a commendable chapter on the dilemmas inherent in multidisciplinary teamwork. There are also chapters describing the rehabilitation problems of mental handicap, old age, and physical disability.

There is a certain amount of duplication; in the chapter on psychological approaches, for example, three pages are devoted to assessment which is also discussed elsewhere. The focus of the book could have been considerably sharpened by the omission of sections on the aetiology, clinical picture, and diagnosis of schizophrenia.

"Common sense" is a recurring phrase in this book and it characterises much of its message. The book is likely to whet the student's appetite for further reading.

MOUNIR EKDAWI, *Consultant Psychiatrist,*
Netherne Hospital, Surrey

The Adolescent Unit Work and Teamwork in Adolescent Psychiatry. Edited by DEREK STEINBERG. Chichester: John Wiley & Sons. 1986. Pp. 229. £12.50.

Adolescent units are complex places where role diffusion, dependent on the personalities and proclivities of the staff, obscures the underlying structure and purpose. This puzzles the observer who has to understand the implications in order to adopt ideas for use in his own work. Yet some form of cross-fertilisation is essential if adolescent units are to be the cornerstone in the growing network of services the Hospital Advisory Service describe in 'Bridges over Troubled Waters'. In the absence of a steady influx of trained staff, it is too easy for a unit to become inbred and isolated. An alternative is to turn to written accounts. Unfortunately, the usual text presents too simple and one-sided a perspective to be useful to the reader who wishes to introduce its ideas to a unit. However, this book notably differs; each chapter is written by one of 21 staff, most of them at the Bethlem Hospital, to give not just a clear and vivid account of their work with some theoretical background, but also how it dovetails with that of others. That this is a very coherent book is an editorial achievement which makes it possible to understand how all these people might knit together to form a team.

Facets of unit management are well covered – the support, supervision, and training of nursing staff; staff groups; medical training and research; as well as the central part played by the unit secretary.

My initial feeling was one of envy for the staffing and resources available to this unit. However, I found this book such a fertile source of ideas that not only did I order another copy for circulation, but it was brought home to me how essential it is to have a centre such as this to serve as a teaching base. Any retrenchment will be a national loss.

I am impressed by the evenly high standard throughout: no chapter was a disappointment. It is easily read and I would recommend it to anyone of whatever discipline who is working in, or touring, an adolescent unit.

T. P. BERNEY, *Consultant Psychiatrist,*
Prudhoe Hospital, Northumberland

The Psychodynamics of Medical Practice. By HOWARD F. STEIN. Los Angeles: University of California Press. 1985. Pp. 190. £14.50.

Stein is a psychoanalyst and medical anthropologist whose book is about the countertransference in medical work. In educational sessions with family doctors and medical students he found its role underestimated. (He defines it widely: "I use the term countertransference to mean all non-rational elements of the physician's work"). So one chapter is "an ethnographic odyssey in which I describe how I discovered the importance of countertransference in the daily work of the family physician and the significance of the unconscious in the dynamics of the physician's role". This is characteristic of the whole book, which shows the author impressed by his own discoveries and overestimating their originality. Thus his exposition of psychoanalytic theory and descriptions of the psychodynamics of the doctor-patient relationship in complex cases in family or specialist medical practice were preceded by Balint in *The Doctor, His Patient and the Illness* over thirty years ago. Stein tends to be repetitive and stodgy in style, and nearly always he is speaking in his own voice. Balint's book was crisply written, memorable, and did its author's job very modestly by using largely the general practitioners' contributions to develop the theme. Today's students will find this book heavy going. Balint is still in print – if money is short, buy a fresh copy for the library to attract their attention.

A. C. SMITH, *Consultant Psychiatrist,*
Greenwich District Hospital, London

Body Image, Self-esteem, and Sexuality in Cancer Patients (second revised edition).Edited by JEROME M. VAETH. Basel, Switzerland: Karger. 1986. Pp. 153. SFr. 79, DM 95, US$33.75, £24.70.

The impact of cancer and cancer treatments on the sexual lives of patients is the predominant theme of this book. Based on a symposium held in San Francisco, the book contains useful information about specific problems facing patients with gynaecological cancers, breast cancer, head and neck cancers, and cancers of the bowel, prostate, testis, and penis. A welcome feature is the participation of patients in the symposium. Their experiences, frankly and often movingly told, provide a sharp reminder to clinicians of deficiencies in current management of cancer patients. Attempts to remedy some of these deficiencies by methods ranging from psychological intervention to surgical procedures such as breast reconstruction and implantation of penile prostheses are outlined. One controlled study is described, in which significant short-term benefits are reported for women with gynaecological cancers treated by crisis intervention counselling.

Certain criticisms are warranted. The omission of an Index is a disadvantage. Occasionally, unrestrained enthusiasm appears to overwhelm clinical common sense. For example, one author recommends that women with pelvic cancer admitted to hospital for major gynaecological surgery should be questioned regarding the frequency of oral, anogenital, and masturbatory activities. The mind boggles. More serious is the use of the label "ostomates" to designate patients with stomas. To stigmatise patients in this way is likely to cause distress by increasing their sense of social isolation. But notwithstanding these criticisms, the book can be recommended for the pertinent, painfully honest comments by patients as much as for the contributions by physicians, psychiatrists, and other professionals.

STEVEN GREER, *Reader in Psychological Medicine, King's College School of Medicine and Dentistry, London*

Biologic Response Styles: Clinical Implications. Edited by HOWARD KLAR and LARRY J. SIEVER. Washington: American Psychiatric Press. 1985. Pp. 95. $12.00.

This volume is said to have been written with a view to filling 'a critical educational gap' relating to a failure to integrate psychobiological advances with the clinical thinking of trainees in psychiatry. Although the editors express satisfaction with their trainees' responses to the approaches described in this small volume I do not think it would be warmly received by the average trainee in this country. Indeed, I should be sorry if it were. In spite of its brevity the content of the book is wide-ranging, covering Harlow's work on monkeys and other later experiments in the same field, the study of neonatal behaviour, and the relationships of many biological variables to a variety of patterns of behaviour. The tone of the chapters is uniformly optimistic and there is no attempt in any of them to provide a balanced assessment of the literature – indeed, one of the authors concludes his chapter with the disarming and accurate statement, "The story is far from complete and I have not addressed some major disagreements among researchers in this area". The book is of some interest as a series of speculative essays, and some readers may find them a striking example of transatlantic English. I could not however recommend this volume for educational purposes for trainees in psychiatry.

EVE C. JOHNSTONE, *Honorary Consultant Psychiatrist, Northwick Park Hospital & Clinical Research Centre, Middlesex*

To Provide Safe Passage: The Humanistic Aspects of Medicine. Edited by DAVID RABIN and PAULINE L. RABIN. New York: Philosophical Library. 1985. Pp. 258. $19.95.

David Rabin was a professor of medicine and of obstetrics and gynaecology who died of amyotrophic lateral sclerosis at the age of 49. In partnership with his wife, who is a psychiatrist, he has written movingly about how he was rejected by his colleagues once they discovered he was incurably ill. This devastating and bewildering experience prompted him and his wife to explore the 'caring' component of medicine as opposed to the 'curing' component: in other words 'to provide safe passage' through illness.

Their 6 chapters are supplemented here by 14 by others, dealing with different aspects of caring, including chemotherapy for cancer, doctors and cancer, hospices, management of intractable pain, attitudes towards mental illness and mental retardation, genetic counselling, death, and dying.

Many of the contributors have been allowed to be wordy, relying on generalisations rather than precise observations. But there are exceptions, such as the chapter on genetic counselling; and of course the Rabins' chapter, Compounding the Ordeal of ALS: Isolation from my Fellow Physicians, which is stark and direct and should be read as a warning by all doctors. Overall the book is a useful introduction to these important topics, and (in paperback) could be recommended to medical students.

GLIN BENNETT, *Consultant Senior Lecturer in Mental Health, University of Bristol*

Human Development (3rd edition). By ERIC RAYNER. Hemel Hempstead: George Allen & Unwin. 1986. Pp. 300. £8.95 (pb), £22.50 (hb).

This is the third edition of a text well known to those who have had to study psychology as a part of their professional training – to those, that is, who use psychology informally, as part of their work.

For this purpose the book seems well suited. It is clear, easy to read and interesting – it is not abstract, but illustrates most of its points from descriptions of real life that most people can recognise.

The book is psychodynamic, based on the modern psychoanalytic viewpoint, although it does cite other references. This raises a slight doubt in the reviewer's mind: if this is the only book, say, a social worker reads, is it sensible that it be restricted to essentially one viewpoint, however revealing this is? The practicality of the book is emphasised by the examples; these include some modern ones (single parents, divorced parents, and sexual partnerships outside marriage) as well as the old-fashioned domestic issues of rearing children in loving families.

I can recommend this book as one which is humane and clearly written and which gives readers a good psychodynamic overview of human development.

PAUL KLINE, *Professor of Psychometrics, University of Exeter, Devon*

Behaviour Therapy in Primary Care. A Practical Guide. By RICHARD FRANCE and MEREDITH ROBSON. London: Croom Helm. 1986. Pp. 235. £10.95.

The aim is to provide a practical manual for primary care professionals with limited time at their disposal, but who wish to use behavioural methods with their patients. The interventions described are brief, and the emphases are on methods that can be used outwith consultation times and on patients' developing self-help skills. The first section deals with behavioural assessment, data collection and monitoring, and the basic concepts of intervention. Part two deals with the management of clinical problems: anxiety, interpersonal problems, habit disorders, the cognitive-behavioural management of depression, behavioural aspects of general medicine, and difficulties in study, work, retirement, childhood, and old age. Useful articles and books are listed.

The aim is fulfilled. Is it significant that the index contains no reference to illness, mental disorder, psychiatrist, or psychiatry?

GREG WILKINSON, *Honorary Lecturer,*
General Practice Research Unit,
Institute of Psychiatry, London

The Man Who Mistook His Wife for a Hat. By OLIVER SACKS. London: Duckworth. 1985. Pp. 233. £9.95.

Dr Sacks presents a series of case reports of a variety of neuropsychological disorders. These are rich in detail and full of the elegant prose that one has become to expect from the author. The book emphasises the limitations of the statistical approach often applied in the neuropsychological literature. More importantly, Dr Sacks takes neuropsychology out from behind the confines of statements of the location of the lesion and associated cognitive deficits to the impact on the patient's experience of the disorder. The book is essentially within the realm of the phenomenology of illness, full of Dr Sacks' provocative interpretations and insights as he peers into the worlds of people with neurological damage. The book covers case reports of prosopagnosia (whence the book's title is derived), visual agnosia, amnesia, neurosyphilis, and autism, amongst others.

This is, however, not a book for those who wish to add to their 'knowledge' of neuropsychology as much as it is for the reader with some interest or curiosity in the range of disorders following neurological damage. The specialist reader is likely to see that the book reflects Dr Sacks' own discoveries of the literature and it is this that may blunt their confidence in the author. For example, it is surprising to read that the author discovered the literature on visual agnosias & prospagnosia only after he completed the book! These concerns should not detract from the book's major contribution, which is to broaden our appreciation of the experience of these unusual and often bizarre disorders.

S. NEWMAN, *Senior Lecturer in Psychology,*
Middlesex Hospital Medical School, London

The Dilemma of Abortion. By EDWIN KENYON. London: Faber & Faber. 1986. Pp. 283. £6.50.

This rewarding Faber paperback by an Oxford academic and clinical psychiatrist integrates two fields of interest, one universal and one topical, by reviewing philosophical and religious attitudes to the human foetus and its rights throughout recorded history and linking them to a detailed, impressively up-to-date account of legal, medical, political and economic issues affecting pregnancy termination today.

In a presentation aimed at general readers as well as health specialists the perspective is broad, but the prose is precise, factual, lucid and elegant. There are manageably succinct references, mostly to prestigious sources. Dr Kenyon writes with a restrained passion, and the humanity and scholarship of his approach are evident from the book's first page, which carries a touching eighteenth-century poem to an aborted child:

> ..."Love, spite of honour's dictates, gave thee breath;
> Honour, in spite of love, pronounced thy death."

Considerations other than honour are nowadays liable (and in many settings, including Britain, likelier) to decree the death of an embryo or foetus: convenience, change of mind, the antenatal detection of disease, the suspicion of genetic defect, pressure from parents, pressure from grandparents, state intervention (as in China), being not of the preferred sex (as, we are warned, among certain cultural groups nearer home), poor housing, poverty, maternal overburdening, maternal age, and psychiatric illness. The author discusses them all, many with examples from his clinical experience. He describes the contributions made, and solutions offered, by embryologists, diagnosticians, family planning experts, lawyers, and psychiatrists. He summarises the attitudes towards contraception and abortion of the major world religions, theocentric or secular, and anybody who has ever had to establish rapport with a client of different background in these sensitive areas will be grateful for his guidance.

The book is pragmatic, objective, and tremendously informative. At £6.50, it deserves a wide sale.

MARGARET J. LITTLE, *Associate Specialist,*
Stobhill General Hospital, Glasgow

Divorce Therapy. Edited by DOUGLAS H. SPRENKLE. New York: The Haworth Press. 1986. Pp. 184. $29.95.

The book does not, as the title suggests, recommend divorce as a therapeutic procedure; rather, it acknowledges that, since divorce abounds, the therapist needs to be equal to the task of successfully steering people through it. Also published as Vol. 1, Nos. 3/4 of the Journal of Psychotherapy and the Family, the book comprises twelve concise sections, the last being an excellent annotated bibliography.

Divorce, it is proposed, like grief, with which it has a great deal in common, is divisible into three stages: the pre-divorce decision-making stage, the divorce restructuring stage, and the post-divorce recovery stage. I was left with the distinct impression that one of the principal objectives of therapy is to keep each individual moving through this sequence. I was impressed by the deceptively simple aphorism of Marcia Brown that once the reality that life will never be the same again hits home the client is faced with another reality – that what is not the same will inevitably have to be different.

Those who seek to understand relationships need also to concern themselves with relationships in transition. In systemic terms divorce involves the decoupling and recoupling of a variable number of family members, and not all members are decoupling or recoupling to the same extent or at the same rate. While focusing on the specific area of divorce, the book in fact is adding richly to a more general knowledge of family dynamics. I would therefore recommend that it be read not just by a specialist minority.

JOHN BIRTCHNELL, *Scientific Officer and Senior Lecturer, MRC Social Psychiatry Unit, London*

New Clinical Concepts in Marital Therapy. Edited by OLIVER J. W. BJORKSTEN. Washington: American Psychiatric Press. 1985. Pp. 165. $12.00.

This monograph emerged from a symposium held at the annual meeting of the American Psychiatric Association in May 1984 and represents the views of seven contributors. Although the last two chapters deal with the treatment of marital dysfunction, the book is not intended as a textbook of marital therapy. The aim is to inform readers about areas of marriage, as it is observed in the United States, which are currently considered to be important and of relevance to psychiatrists.

Five areas are covered. First there is an overview of sociodemographic aspects of contemporary American marriage (T. J. Stewart, O. J. W. Bjorksten and I. D. Glick) which provides a critical assessment of marital trends, pointing out how erroneous conclusions are often drawn from simplistic handling of available data. The next two chapters provide a competent scan of the relationships found in America, between marital status and psychiatric morbidity (R. T. Segraves) and between marital status and health (O. J. W. Bjorksten and T. J. Stewart). There follows a discussion (C. J. Sager) of the psychiatric implications of the phenomenon of the reconstituted family which have been brought into prominence by the current high remarriage rate, accompanied by a description of one form of intervention. Finally, there is a chapter (D. C. Polonsky and C. C. Nadelson) on an approach to couples therapy in which the authors illustrate how therapists can integrate different therapeutic models to deal effectively with changing clinical realities. The major theoretical positions dealing with the therapy of couples are not reviewed, the assumption being made that readers will be familiar with them.

The explanatory hypotheses used to make sense of the wide range of information cited express the accumulated experience of the schools of thought represented by the authors. Although not all psychiatrists may agree with these views, the monograph gives a succinct and refreshing overview of data of value both to clinicians and to research workers.

DOROTHY H. HEARD, *Lecturer, St James's University Hospital, Leeds*

Evoked Potentials: Frontiers of Clinical Neuroscience Volume 3. Edited by ROGER Q. CRACCO and IVAN BODIS-WOLLNER. New York: Alan R. Liss. Pp. 551. £70.00.

Evoked response techniques have provided an added impetus to the investigation of many types of patient including those with psychiatric disorder. This multi-authorship book with a firm editorship provides a comprehensive review with sections on basic aspects, methodology, animal models, and anatomy, as well as biochemistry and pharmacology. On the clinical side neurological, neurosurgical, and paediatric aspects are presented at some length. It is a pity therefore that psychiatry does not have a broad coverage and odd that the 'expectancy wave' (now called the CNV), a feature first noted to relate to 'mental state', is not even mentioned, although the P300 component is discussed, while learning disabilities and related matters as well as dementia are assigned chapters. This is therefore not a book for the general psychiatrist, but for those who have a special interest in clinical neurophysiology. For them there is much to be gained from this well-produced and otherwise comprehensive volume.

D. F. SCOTT, *Consultant in Neurophysiology, The London Hospital*

Research in Schizophrenic Disorders: The Stanley R. Dean Award Lectures Volume I.By ROBERT CANCRO and STANLEY R. DEAN. Lancaster: MTP Press. 1985. Pp. 287. £42.50.

This is the first of two volumes reprinting the lectures given annually from 1962 to 1982 by holders of the Dean Award. The award was intended to acknowledge major research contributions to schizophrenia. It is said that very little of importance has been done on schizophrenia in the last twenty years that has not involved an awardee; surprisingly, only one of the awardees is British.

Volume I relates to diagnosis and to social and familial factors in aetiology.

The papers that still retain most interest are those by Kanner on infantile autism, Manfred Bleuler on the natural history and on the children of schizophrenics, Langfeldt on diagnosis and prognosis, and Mednick and Schulsinger on studies of children at high risk.

Some of the authors have taken the opportunity of republication to comment on their papers. Bleuler summarises one of his main findings: on average, psychosis shows no change for the worse after a duration of five years. He believes that nowhere is sufficient assistance given to the children of schizophrenics.

Langfeldt's comments include the surprising statement that as late as 1980 he was led to realise that the terms depersonalisation and derealisation are not used in Anglo-American psychiatry in the same way as he used them, which was to describe certain delusions of passivity.

The book is of some historical interest and also of value because it makes the writings of the non Anglo-Americans accessible.

J. COOKSON, *Consultant Psychiatrist, The London Hospital (St Clement's)*

Infant Psychiatry: An Introductory Textbook. By CLAUS MINDE and REGINA MINDE. London: Sage Publications. 1986. Pp. 197. £19.75 (hb), £10.00 (pb).

This is a book dealing with the child under 3 from a psychological and psychiatric viewpoint. The historical review is most engrossing and the summary of theories of child development outstanding in its comprehensive yet brief account. It is broad-based and eclectic, drawing on ideas and research from many fields.

I read this book with complete satisfaction until page 99. From then on, I found myself in difficulties with their classification. Particularly disappointing was the sudden failure, after such circumspection and balance in the earlier chapters, to look critically at their diagnostic categories. The Reactive Attachment Disorders of Infancy are, of course, part of DSM-III but the authors suggest making this an even less well defined category than it is currently. Then there is a wholly unsatisfactory group of "Disorders in Behavioural Organisation"; no evidence is offered as to the validity of such a grouping. To most of us, this grouping refers to children who are very difficult temperamentally.

However, leaving aside the unsatisfactory classification, all the chapters on assessment and treatment, including those just mentioned which do have clinical appeal, make interesting reading and would add to most people's understanding and ways of intervening in problems in this age group. In particular, it adds to one's confidence in assessing young babies and early parenting difficulties.

I would recommend this book to anyone who wants to focus their thoughts on the specific problems of babies and the young child. Read with the reservations mentioned in mind, it makes a very good introduction.

CLAIRE STURGE, *Consultant Psychiatrist,*
Northwick Park Hospital, Middlesex

Institutions Observed: Towards a New Concept of Secure Provision in Mental Health. By LARRY GOSTIN. Oxford: Oxford University Press. 1986. Pp. 179. £6.50.

Larry Gostin's latest offering is something of a broadside, in which he reviews the inadequacies of the various institutions that cater for offender and/or disturbed mentally disordered patients. Prisons, the new regional secure units and local mental hospitals are all criticised, but he reserves his biggest salvoes for the special hospitals. Gostin says (and who would disagree?) that there is no effective, national organisation of services for mentally abnormal offenders; patients end up in the wrong place – in particular in the wrong institution. A succession of reports has not helped, and there is a preoccupation with secure accommodation.

Gostin argues for a service that provides "fluid security"; a flexible system of care, locally available, that will meet the changing clinical needs of the patient during the course of his illness. Locating patients according to assessments of dangerousness, he says, are bound to fail; dangerousness itself is a fluid, not a fixed, quality. Each chapter concludes with recommendations of which many are sensible, some are puzzling and a few are naive. Brief commentaries are provided at the end by Viscount Colville, who homes in on the particular, and by Dr Tim Harding, who confines himself to general principles. Few of his criticisms are new but Gostin puts his case together with customary skill. This is a book for those who are more interested in planning services than in designing institutions. The King Edward's Hospital Fund is to be congratulated for supporting a project and publication on this important topic.

Psychiatry, University of Edinburgh

Psychotherapy in a New Key: A Guide to Time-Limited Dynamic Psychotherapy. By HANS H. STRUPP and JEFFREY L. BINDER. London: Harper & Row. 1985. Pp. 333. £22.50

In line with the need to specify what psychotherapists actually do, this practical guide does exactly that for a form of time-limited dynamic psychotherapy (TLDP) developed over 15 years by the Vanderbilt team. The book is clinical and practical, the backing research having been reported elsewhere. Brevity, focus, the attempt to understand and to rectify destructive past relationships through a good therapeutic relationship, and the techniques used to achieve this are set out in detail with clinical examples.

There are now a number of clinically soundly-based dynamic psychotherapy systems: Malan, Mann, Davanloo, Sifneos, Luborsky. Whether TLDP has staying power is impossible to know at this point. However, this well-written book is an important contribution, useful both to psychotherapy trainers and to trainees.

SIDNEY CROWN, *Consultant Psychiatrist,*
The London Hospital

Psychological Aspects of Genetic Counselling. Edited by ALAN E. H. EMERY and IAN M. PULLEN. Orlando: Academic Press. 1984. Pp. 236. $14.00/£9.00 (pb), $32.00/£20.00 (hb).

This is a well written and edited book that is specifically aimed at helping genetic counsellors improve their counselling skills. It will also be of interest to other professionals who work with individuals who need counselling. There is not very much information in the book about the genetics of specific diseases, and readers who are seeking this information will need to find it elsewhere.

The book adopts the position that individuals who want counselling will display very different reactions even when faced with the same genetic dilemma. Therefore an awareness of the range of psychological mechanisms that can develop from stress such as depression, guilt, and denial is very important. The authors of the various chapters do however display different approaches to this issue. Falek adopts a relatively hard-nosed attitude, seeking to ensure that counselling is efficacious. The other chapters are concerned with marital pathology, early infant loss, Down's syndrome, mental handicap, physical handicap, Huntington's disease, infertility, sterilisation, artificial insemination, and prenatal diagnosis. All these chapters are thoughtful and humane. Some chapters are delightfully enthusiastic, for example the one on Huntington's disease.

Many psychiatrists might be interested in reading this book because even if they do not provide counselling, it shows how geneticists and others have learnt to describe psychological mechanisms in a practical, non-dogmatic manner.

Published by authority of
The Royal College of Psychiatris

ISSN 0007-1250

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary.*

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al, British Medical Journal,* 7 May 1983, **286**, 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins,** and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that . . . '

DURKHEIM, E. (1897) Le Suicide. Paris. Translated (1952) as Suicide: A Study in Sociology, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. British Journal of Psychiatry, **124**, 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970) Education, Health and Behaviour. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In Pathology and Treatment of Sexual Deviation (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal,* should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

The Clinical Roots of the Schizophrenia Concept

Translations of Seminal European Contributions on Schizophrenia

Edited by **J. CUTTING** and **M. SHEPHERD**

The original descriptions and ideas of those psychiatrists who established the concept of schizophrenia are of crucial importance in the continuing struggle to understand the condition. Here are collected the most important articles from Kraepelin to Janzarik, selected for their historical interest and contemporary relevance.

1986 238pp. 0 521 26635 1 **£27.50 net**

The Long-Term Treatment of Functional Psychosis

Needed Areas of Research

T. HELGASON

Organisational, patient and public health aspects of functional psychoses are described in this book, and neglected areas highlighted. The workshop from which the book derives was organised by the European Medical Research Council and was attended by leading workers from throughout Europe.

Children, Youth, and Families

Reconsidering the Relationship between Research and Action

Edited by **ROBERT N. RAPOPORT**

This book examines the connections between research and action to improve the situations of children, youth, and families. It discusses how the paths of social scientists and those engaged in programme development have diverged since the 1950s and 1960s with a resultant inhibition of action initiatives, on the one hand, and a stagnation in the quest for new knowledge, on the other.

1985 320 pp. 0 521 30143 2 **£27.50 net**

Life Events and Psychiatric Disorders

Controversial Issues

Edited by **H. KATSCHNIG**

This collection of essays gives a critical evaluation of current research on the relationship between life stress and the origin of functional mental disorders. Depression is especially emphasised, and its division into a biological and a psychosocial type is considered.

1986 280 pp. 0 521 25596 1 **£32.50 net**

The Reality of Mental Illness

SIR MARTIN ROTH and **JEROME KROLL**

This book is psychiatry's reply to the diverse group of antipsychiatrists, that has made fashionable the view that mental illness is merely deviant behaviour. It establishes, that mental illness has been recognised in all cultures since the beginning of history and goes on to explore the philosophical and medical basis for psychiatry's diagnosis and treatment of mental illness.

1986 128 pp. 0 521 32151 4 **Hc £22.50 net**
0 521 33761 5 **Pb £7.95 net**

Law, Psychiatry and Morality

Essays and Analysis

ALAN A. STONE

Written specifically for legal and mental health care professionals, Dr. Stone's book attempts to clear up the many ambiguities in the relationship between law and psychiatry, and covers such issues as political misuse of psychiatry, psychology and violence, psychiatry and the U.S. courts, sexual exploitation by psychotherapists, and morality and psychiatry.

1986 291 pp. 0 521 33954 5 **Pb £12.95 net**

Mental Disorder and Legal Control

PHILIP BEAN

The 1983 Mental Health Act (England and Wales) introduced far-reaching changes in the control of mentally disordered people. By examining these in terms of the admission of patients, their control in hospital and the community, and their rights as regards Consent to Treatment and legal redress, this series of essays covers topics of international importance.

1986 207 pp. 0 521 30209 9 **£27.50 net**

CAMBRIDGE

PROGRESS IN PSYCHIATRY

A New Series From The American Psychiatric Association in Association with Cambridge

Treatment of Affective Disorders in the Elderly

Edited by **C. A. SHAMOIAN**

Based on material presented at the 1985 APA Annual Meeting in Dallas, Texas, this book presents current approaches to the biology, diagnosis, treatment and treatment outcome of depression in the elderly, and as such is the most authoritative recent work on this important clinical field.

1986 84 pp. 0 521 33274 5 **£15.00 net**

Post-traumatic Stress Disorder in Children

Edited by **S. ETH** and **R. S. PYNOOS**

PTSD was included as an Axis I diagnosis in DSM-III, thereby accelerating research in this new field. This volume assembles the leading participants in the field in a discussion of the often profound impact of traumatic occurrences on the lives of children.

1986 186 pp. 0 521 33271 0 **£15.00 net**

Medical Mimics in Psychiatric Disorders

Edited by **I. EXTEIN** and **M. S. GOLD**

This volume advances a psychosociobiological model that may lead to more effective treatment of patients. The papers collected have shed new light on the biological variables influencing behaviour which are often critically responsible for symptom development.

The Borderline: Current Empirical Research

Edited by **T. H. McGLASHAN**

Ever since specifiable diagnostic criteria for borderline personality disorders were introduced in DSM-III, clinical research in this area has blossomed. This book offers a sampling of the central and most important current empirical research and helps to extend understanding of this common and perplexing clinical entity.

The Psychiatric Implications of Menstruation

Edited by **JUDITH H. GOLD**

A comprehensive update of the pertinent research in this field which provides a diagnostic schema, a review of treatment methods and suggestions for further research.

1986 102 pp. 0 521 33272 9 **£15.00 net**

Can Schizophrenia be Localised in the Brain?

Edited by **NANCY C. ANDREASON**

This monograph addresses the possibility that schizophrenia may be due to relatively specific abnormalities in relatively specific brain regions, and that varying symptoms of schizophrenia may reflect different localizations.

1986 87 pp. 0 521 33275 3 **£15.00 net**

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

NEW PUBLICATION

GASKELL

The Publications Section of the Royal College of Psychiatrists
CONTEMPORARY ISSUES IN SCHIZOPHRENIA

Edited by Alan Kerr and Philip Snaith

ISBN 0 902241 14 1 Pp 480 £17.50

This book presents a comprehensive selection of re-edited papers published in the British Journal of Psychiatry during the last ten years, together with a number of specially commissioned reviews of current knowledge in schizophrenia. The subject is considered under seven sections: general and historical concepts; classification and phenomenology; organic aspects; genetic aspects; social aspects; treatment; and outcome.

Contemporary Issues in Schizophrenia, published February 1986, at £17.50 postage free. Orders with cheques should be sent to: Editorial Office, Royal College of Psychiatrists, 17 Belgrave Square, London SW1X 8PG.

Conference Secretary,
Greaves Hall Hospital,
Banks, Nr Southport.
Tel: (0704) 27451, extn. 357.

THE TAVISTOCK CLINIC

THE MILAN SYSTEMIC APPROACH TO FAMILY THERAPY

A multi-disciplinary half day course to be held at the Tavistock Clinic on Tuesday afternoons for 3 terms beginning in October 1987 with an option for a second year. This course includes family work under live supervision, theoretical and skills seminars. Membership is open to professionals who have had some training in Family Therapy and have an established family therapy practice in their agency. Applicants must have prior experience and a particular interest in developing the Milan Systemic Approach.

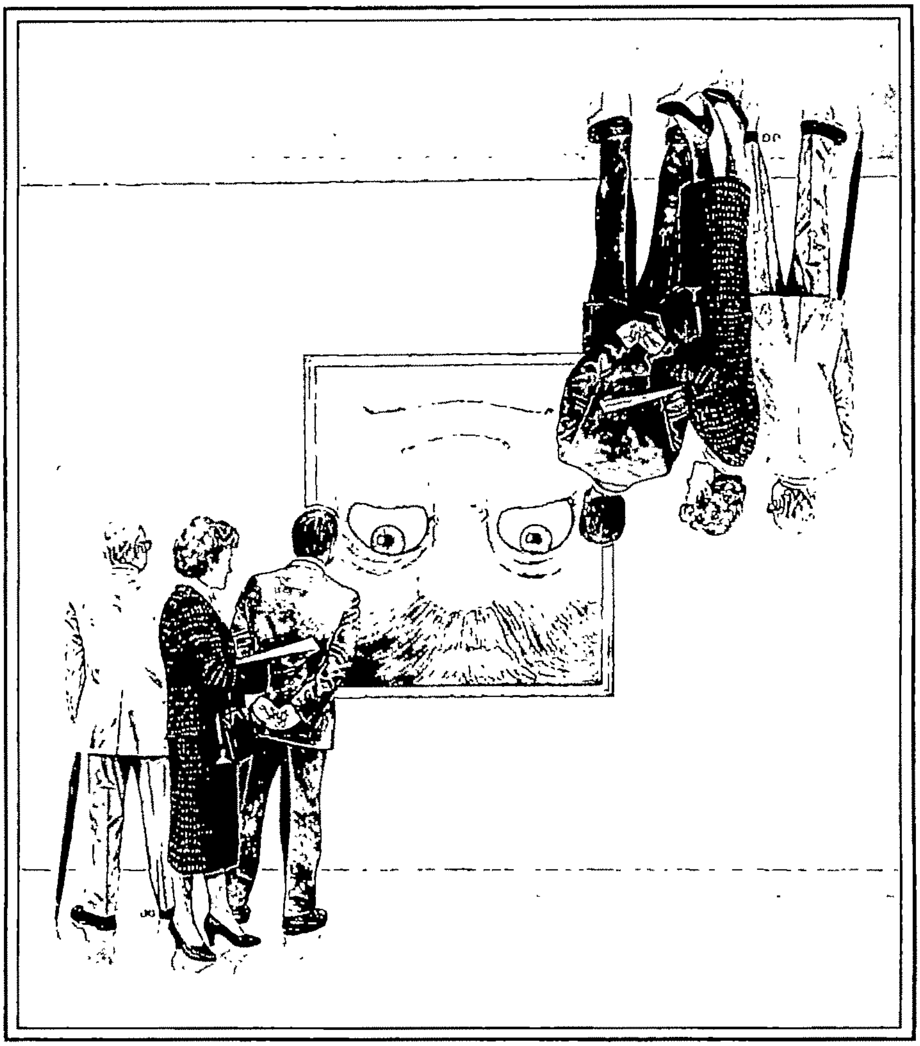
Further information and application form available from:

The Training Administrator,
The Tavistock Clinic,
120 Belsize Lane,
London, NW3 5BA.

Tel: 01-435-7111, Ext: 313 or 469.

A general prospectus of training is available upon request.

Modecate Abbreviated Prescribing Information. Indications: Treatment of psychotic disorders. **Dosage – Modecate injection 25mg/ml.** Most patients are successfully maintained within the dosage range 12.5mg (0.5ml) every five weeks to 100mg (4ml) every two weeks. For full dosage information see Data Sheet. **Modecate concentrate injection 100mg/ml.** Adult patients found to require larger volumes of Modecate 25mg/ml may be transferred directly to the equivalent dose of Modecate concentrate on the basis that 1ml Modecate concentrate is equivalent to 4ml Modecate. **Contra-Indications.** Patients with marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, or severe cardiac insufficiency. **Precautions.** Care should be taken in patients, particularly the elderly, who exhibit marked extrapyramidal reactions to oral phenothiazines. **Side effects.** Mainly extrapyramidal reactions. Drowsiness, lethargy, dryness of the mouth and mild hypotension may occur. **Product Licence No's and Prices. Modecate injection 25mg/ml.** PL 0034/5046. 10 x 1ml ampoule £25.20 **Modecate concentrate injection 100mg/ml.** PL 0034/0189. 10 x 0.5ml ampoule £49.99 5 x 1.0ml ampoule £48.86. Modecate is a Trade Mark of E. R. Squibb & Sons Ltd. Further information available from: Technical Services Department, E. R. Squibb & Sons Ltd., 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. Tel: 01-572 7422.



TRIED AND TRUSTED

19 years ago, E. R. Squibb & Sons helped lead a revolution in the community based treatment of schizophrenia when they introduced the depot neuroleptic concept.
Since then worldwide clinical experience has confirmed the efficacy and safety of Modecate in over 800,000 patients.
Modecate is now regarded by many psychiatrists as the standard depot neuroleptic.

MODECATE®

25 mg/ml

100 mg ml

FLUPHENAZINE DECANOATE

Modecate is available in two strengths, allowing a wide dosage range with convenient injection volumes.
Most patients can be controlled with an injection at intervals of 3 weeks or more.[1]
Modecate is less expensive than other depot neuroleptics when comparing equipotent doses.

Review Article

The Burden of Care:
The Impact of Functional Psychiatric Illness on the Patient's Family

G. FADDEN, P. BEBBINGTON and L. KUIPERS

This paper reviews the literature on the effect of severe mental illness on other members of the patient's family. The burdens of caring for a patient at home are considerable. They often affect the caring relative's social and leisure activities, and financial problems arise frequently. Relatives have difficulties in understanding and coming to terms with illness-related behaviour. 'Negative' symptoms are often a particular problem. Despite their burden, relatives do not complain much, although they receive little support, advice or information from the professionals engaged in treating the patient; much is now known about the difficulties relatives face, but we still need to know how they can best be helped. Failure to do this will have bad effects on both relatives and patients.

Most studies of the families of psychiatric patients have been aetiological. Family processes have typically been examined because of an interest in the effect of the family on the patient's illness. The view that relatives may have a deleterious influence on the course of illness is reflected in the behaviour of many mental health professionals in the clinic, who may give an impression of blaming them or of regarding them only as exploitable sources of information.

Comparatively few workers have looked at the impact of a psychiatrically ill member on the rest of the family, or at how they cope with their situation, although the majority of patients now return to live in the community. Indeed, even after many years of illness, as many as 50% of patients remain in contact with relatives (Creer *et al*, 1982). In our view, the existing studies of the effects of mental illness on the family have major implications in the fields both of psychiatric management and of social policy.

The concept of burden

This concept shares characteristics with that of social performance, for one person's poor social performance is another person's burden. Both concepts are relative to social expectations which are likely to be very variable. Thus, as Platt (1981) has emphasised with regard to social performance, measurement can never be entirely satisfactory. Measures of burden likewise remain open to criticism (Platt, 1985).

The existence of a burden indicates the breakdown of the reciprocal arrangements that people maintain in their relationships, such that one person is doing 'more than their fair share'. This may merely result in them taking on greater proportion or number of shared tasks, but it may also restrict their activities outside the relationship. This change in pattern can be assessed against approximate norms. In addition, it is often accompanied by subjective dissatisfaction. At a given level of objective burden, individual levels of distress show considerable variation (Platt, 1985). This further aspect of burden should not be ignored.

The dissection of the concept of burden through the effects on the performance of various roles carried out by the patient's relatives was an approach first used by Mills (1962). Grad & Sainsbury (1963*a*, *b*) advanced the measurement of burden by using a 3-point scale rather than the descriptive sketches given by their predecessors. Hoenig & Hamilton (1966, 1969) made the important distinction between 'objective' burden (e.g. effects on health, financial loss) and 'subjective' burden (the extent to which relatives felt they carried a burden). These techniques were applied by Creer & Wing (1974) in their study of the relatives of patients with schizophrenia. The methods used in the study of burden have now reached a reasonable level of sophistication despite the qualifications concerning measurement (Platt, 1985). A structured account of the behaviour of patients likely to give rise to problems is related to an equally structured assessment of the effects upon relatives and of the ways they have of coping.

Early studies on families of psychiatric patients

The first studies of the demands on the families of those with mental illness were carried out by a group of social scientists in the United States in the mid-1950s (Clausen & Yarrow, 1955). They operated within a theoretical framework developed from studies on deviance, social control and social perception (Schachter, 1951; Bruner & Tagiuri, 1954; Yarrow *et al*, 1955). The impetus for their research was clear:

> Almost no systematically collected data exist to permit an analysis of what happens within the family group when a member develops a mental illness (Clausen *et al*, 1955).

They studied 33 families where the husband was a patient with a diagnosis of psychosis or psychoneurosis. The investigators followed the wife's reaction from the time of her husband's first admission to 6 months after his return home, or to the end of his first year in hospital. This first study highlights a number of important themes which recur in subsequent research and which we will substantiate below.

The extent of burden

Because studies use different criteria for the severity of burden, only the most impressionistic sketch can be given of its extent among the relatives of patients with persistent disorders.

Mandelbrote & Folkard (1961*a*,*b*), in a study of schizophrenic patients, reported the degree to which families were restricted or disturbed by the patient's presence in the home, though it is not clear how they rated these factors. Fifty-five per cent of families were rated as disturbed in some way, though only 2% of relatives reported severe stress. The authors are vague about what they regard as stress on the family, describing typical stress situations as 'those in which the behaviour of the patient upset his family or prevented them from doing certain things'. Another shortcoming of the study is that at follow-up they did not interview the families of those patients (18% of sample) whom it had not been possible to maintain in the community, and who presumably had the most severe effects on their families. The authors found that there were more disturbed families in rural than in urban areas.

In Mills' (1962) study of unselected psychiatric patients, practically all were a source of anxiety to their relatives. More than 50% were described as 'difficult' at home and only 12% caused no practical difficulties. In Grad & Sainsbury's study (1963*a*,*b*) comparing a community-orientated and a traditional service, almost two-thirds of the families had been experiencing hardship because the patient was living at home, and in one-fifth the burden was severe.

Wing and his colleagues (1964) followed the course of 113 schizophrenic patients for a period of 1 year after discharge. Where patients returned to live with their families, social relations were strained in 59% of cases, often to the limit of what would ordinarily be regarded as tolerable.

Waters & Northover (1965), in a 2 to 4-year follow-up of 42 schizophrenic men, similarly reported that many of the patients caused moderate to severe hardship to their relatives in terms of social embarrassment, inconvenience, and behaviour which frightened them or gave rise to tension in the family. Hoenig & Hamilton (1966, 1969) examined both 'objective' and 'subjective' burden. In their study, 76% of patients had some kind of adverse effect on the household.

The impression from these studies is therefore that burden exists and is extensive. This is reflected in the well established finding of high rates of divorce and separation in marriages where one patient is mentally ill. For example, in many cases observed by Brown and his colleagues (1966), the patient's illness had been instrumental in bringing about divorce or separation. The divorce and separation rates quoted in the study were three times the national average for female patients and four times the national average for males. However, in some ways, it is surprising that more marriages do not break up. In the study by Yarrow and his colleagues (1955*a*) several wives had contemplated separation or divorce, but all had decided to give the relationship another try. A similar adherence to the marriage, in the face of considerable difficulties and apparently meagre rewards, was noted by Fadden and her colleagues (1987).

Effects on social relationships

One of the most damaging consequences of living with a relative with a persistent mental illness is the detriment to social and leisure activities. This was noted in the first study of the problem (Yarrow *et al*, 1955*b*): wives consistently believed that mental illness was regarded by others as a stigma and expressed fears regarding social discrimination. In consequence, one-third adopted a pattern of 'aggressive concealment', making drastic changes in order to avoid or cut off former friends, with some going so far as to move to a different part of town. Another third had told only members of the family, or close friends who either understood the problem or had been in a similar situation themselves (Yarrow *et al*, 1955*b*).

A number of other studies have documented the restriction of social activity experienced by those who live with and care for patients with schizophrenia (e.g. Mandelbrote & Folkard, 1961*a*,*b*; Wing *et al*, 1964; Waters & Northover, 1965) and this may be especially marked when the relative is an elderly parent (Leff *et al*, 1982). However, such findings have also been reported for spouses of a group of patients with persistent depressive disorders (Fadden *et al*, 1987). These relatives spent over 60 hours a week in face-to-face contact with the patient and were correspondingly socially isolated. Grad & Sainsbury (1963*a*,*b*) add that the restrictions are not limited to those living with schizophrenic patients. It is not at all clear that the phenomenon of stigma contributes less to this social isolation than it did in 1955.

Financial difficulties

These have been emphasised in a number of studies (Yarrow *et al*, 1955*b*; Mandelbrote & Folkard, 1961*a*,*b*; Mills, 1962; Hoenig & Hamilton, 1966, 1969; Stevens, 1972). To some extent, difficulties may arise because caring for a patient with a persistent psychiatric disorder limits opportunities for an adequate income. The most severe problems, however, occur when the patient was formerly the breadwinner, particularly if circumstances prevent the relative from taking over this role. The extent to which the families of psychiatric patients are impoverished should not be underestimated.

Relatives' attitudes to the illness

Although mental health professionals, by their calling, readily accept that behaviour can be symptomatic of illness, this requires a major shift in attitude for relatives. Clausen and his colleagues (1955) pointed to the difficulties wives experienced in attributing meaning to their husbands' actions. Wives' attitudes about the normality of such unfamiliar behaviour continually altered, probably because of the overlap between the symptoms of mental illness and normal patterns of behaviour. Early interpretations tend to focus on physical difficulties, or character problems such as their husband being weak or lacking in willpower (Yarrow *et al*, 1955*a*). The authors note the psychological impact on the wife of having to consider her own possible role in the development of her husband's disorder, and of contemplating her future as the wife of a 'mental' patient. It is also clear from the study that the wives experienced anxiety, guilt and feelings of rejection towards their husbands as a consequence of the illness.

Most of the relatives described by Creer & Wing (1974) had at various times experienced anger at the way their lives had been spoiled and grief when they recalled what the patient had been like before the onset of illness. In the study of Fadden and her colleagues (1987), many of the spouses of depressed patients expressed a sense of loss, as if they had been physically bereft of the person they had married. Anger and guilt were also prominent.

It is apparent from these accounts and others scattered throughout this literature, that the intrusion of mental illness into the family is a trauma which causes relatives considerable difficulties and with which they are given little help. Moreover, things may not become easier as time passes. Hoenig & Hamilton (1966, 1969) found that the likelihood of some objective burden increased the longer the patient remained ill. Mandelbrote & Folkard (1961*b*) similarly reported that progressively more families were rated as disturbed as time passed during their 4-year follow-up period.

Burdensome symptoms

There is a fairly clear-cut consensus from the available studies regarding the symptoms that relatives find most difficult. A common concern of the relatives in Mills' (1962) study was that patients might be a danger to themselves or others, and problems frequently arose with neighbours as a result of the patients' behaviour. Many relatives complained of disturbed nights, and reported that practical problems caused less difficulties than the patient's 'strange fancies' or 'dumb apathy'. Those patients who did not speak often created more distress than those whose speech was excessive, though the latter caused suffering too. In Grad & Sainsbury's (1963*a*,*b*) study, patients with psychosis presented more of a problem than those with neurotic disorders. The symptoms found to be associated with a rating of severe burden were aggression, delusions, hallucinations, confusion and an incapacity for self-care. However, the problems families complained of most often were not the clear-cut symptoms, such as violent or socially embarrassing behaviour, that are usually associated in the public mind with mental illness, but rather the frustrating, depressive and hypochondriacal preoccupations which the patients exhibited. Brown and his colleagues (1966) found the number of problems and the distress experienced by the relatives of schizophrenic patients were highly related to the degree of disturbed behaviour shown by the patient. Hoenig & Hamilton (1966, 1969) confirmed that relatives most frequently reported both aggressive behaviour and extreme seclusiveness or withdrawal as causing problems.

The symptoms which Creer & Wing (1974) reported as being most problematic for relatives of those with schizophrenia were the 'negative' ones, those associated with social withdrawal such as lack of conversation, underactivity, slowness and having few leisure interests. The other group of symptoms causing problems were socially embarrassing behaviours and the more obviously disturbed behaviours. The fact that relatives find the 'negative' symptoms of schizophrenia most difficult to cope with was again confirmed by Vaughn (1977) who did a content analysis of critical remarks made by relatives. Only one-third of the remarks concerned delusions, hallucinations or other florid symptoms while two-thirds referred to behaviour such as lack of communication, affection, interest and initiative. Relatives typically did not view these deficiencies as part of the illness but as personality attributes which were under the patient's voluntary control. They described the patients in such disparaging terms as 'lazy', 'selfish' and 'useless'.

In depressive illness, there are also symptoms which can in a broad sense be called negative, such as social withdrawal, quiet misery and so on. Fadden and her colleagues (1987) also reported that it was symptoms of this type that relatives found most difficult to deal with, although florid and embarassing behaviour was also hard to tolerate.

A consistent picture emerges from these accounts. Whereas relatives are apprehensive of florid symptoms, it is the suppressive effects of mental illness on behaviour that cause the most problems, and this is partly due to the difficulty which relatives have in attributing such effects to mental illness.

Relatives' burdens and the mental health services

A prominent theme in this literature is the tolerance of relatives, and the relevance of this to the support they receive from the professionals caring for the patient. Mills (1962) noted that relatives accepted their burdens in spite of the great sacrifices involved and, in protecting the patient, endured really difficult behaviour. They sought re-admission only as a last resort. Wing and his colleagues (1964) emphasised that relatives did their best to put up with very disturbed behaviour, complained little and were willing to take on the role of nurse, frequently at the cost of considerable discomfort and distress.

Waters & Northover (1965) also remarked that relatives showed surprising tolerance of disturbed behaviour. Brown and his colleagues (1966) felt strongly that too much was sometimes being asked of relatives who, however, did not complain, either because they were too ashamed to talk about their problems or because they had concluded that no effective help would be offered. It was evident that relatives needed expert aid, which they received only when their difficulties had reached a crisis. Brown and his colleagues (1966) warn against those involved in service provision assuming patients are better off at home because the majority of relatives do not complain: "The fact that there is this lack of complaint cannot be interpreted as a justification of community care".

Hoenig & Hamilton (1966, 1969) found an interesting discrepancy between objective and subjective burden. Almost a quarter of the households carrying a good deal of objective burden made no complaints of subjective burden, reflecting once more the families' tolerance towards the mentally ill member. A more disturbing finding was that, among those people who felt that nothing more could be done for them, three-quarters suffered some objective burden, and almost a half complained of subjective burden. This shows the lack of expectation of help on the part of these relatives, and in fact only 7% of relatives in the study made any complaint about services.

Creer & Wing (1974) reported that the relatives of their schizophrenic group rarely complained about their difficulties for reasons of shame, guilt, denial of problems or unfavourable experiences when they had sought help. Virtually none of the relatives had received advice from professionals on the management of difficult behaviour, and those who had worked out methods of dealing with problems did so by a painful process of trial and error. The authors concluded that there is no general recognition of the fact that relatives were functioning as 'primary care' agents, and suggested the introduction of a counselling scheme that would provide families with information and strategies for dealing with difficult situations.

In their further study of chronic patients of whom over 40% were cared for or supported by relatives, Creer and her colleagues (1982) also looked at how relatives felt about providing support—whether they were content, resigned or dissatisfied. It was clear that the situation reported by Creer & Wing (1974) was largely unchanged. These relatives were coping with very difficult behaviours, for the most part without complaint. The authors were particularly concerned about the failure of professionals to meet relatives' needs, including those for practical assistance and advice, for emotional support, and for providing them with occasional breaks from their demanding task. They pointed out that no professional group was concerned with the problems of relatives in their own right, and that services were almost exclusively patient-oriented.

Wing (1982) reiterated the problems faced by relatives who have no training in dealing with difficult behaviour, who unlike hospital staff are 'on duty' all the time, and whose emotional involvement with the patient makes it difficult for them to remain neutral in their interactions with patients. Once again he advocated that professionals should make themselves aware of the real problems that arise in families.

A number of other authors have drawn clear inferences from their findings for the way services are provided for the families of mental patients. Mandelbrote & Folkard (1961*a*,*b*) recommended that the burden on families should be lightened by arranging facilities to take the patient from the home for part of the day, and that more social workers were needed to deal with interpersonal problems within the families.

Mills (1962) was also of the opinion that relatives needed relief part of the day, at night or during crises, and that these patients remained in the community only at the cost of considerable hardship. She concluded:

> If patients are more often to be treated from their own homes, then their families should not have to bear without help the severe practical problems and strains.

Waters & Northover (1965) regarded the lack of sustained support of patients' families as one of the important shortcomings of the community after-care provided for the patients. These papers were both written over 20 years ago, and there is no evidence that service provision has changed markedly. The implications are stark.

The behaviour of professionals towards relatives

It is clear that professionals do not provide much help for relatives. The early American study described above (Clausen & Yarrow, 1955) examined how this lack of provision was related to the communication between wives and their husbands' psychiatrists, and to the attitudes which each held towards the other (Deasy & Quinn, 1955). An analysis of the requests made of the psychiatrists by wives revealed that most (71%) were efforts to secure information regarding aetiology, diagnosis and prognosis, and advice on how to deal with the patient when he returned home. The remaining requests were either for help with personal problems (9%) or attempts to change the course of hospitalisation (20%). However, in almost two-thirds of cases, the wives expressed dissatisfaction because they were not provided with the information they required or because the doctors were inaccessible. Most psychiatrists considered it reasonable that wives should expect information, and were aware that they did not always fulfil the needs of patients' families, either because of their heavy workload or because the nature of psychiatric illness made it difficult to answer many of the questions posed. Nevertheless the 23 psychiatrists interviewed focussed their attention almost exclusively on their patients, and contacted relatives only at the early stages of hospitalisation to secure information. Although they agreed that wives needed help from some source, they did not see this as their responsibility. When asked to describe the characteristics of a 'good' wife, they used terms such as "she has insight into her husband's condition, lets the doctors alone, co-operates with the hospital's plans for the patient". A 'bad' wife on the other hand was someone who "exhibits signs of emotional distress, tries to thwart the hospital, takes up a great deal of the doctor's time". Deasy & Quinn (1955) reported that the psychiatrists frequently felt they had to protect the patient from his wife as they believed that factors in the husband–wife relationship had contributed to the patient's illness.

It can be imagined that these attitudes, whatever their level of justification, do help to meet the relatives' needs. Although no subsequent study has looked specifically at professional attitudes, these themes continue to arise in reports of relatives' dealings with staff.

Community care and the burdens of relatives

The impetus for many of the studies described here was provided by the move towards community care. It is clear that if more patients are in the community, more relatives will have to care for them and will experience a consequential burden. A worrying finding, however, emerges from the first study specifically designed to examine the differential effects of a community-oriented service and a more traditional hospital-based service on the relatives of psychiatric patients (Grad & Sainsbury, 1963*a*,*b*). Not only were more people caring for relatives in the first scheme, but their degree of burden was actually greater. The authors speculated that this was because the burden on families in the traditional hospital approach was lightened by regular visits to the homes from the social work staff, while this was not the case in the community-based service.

Sex differences

Few investigators have reported on the differential effects of the sex of the relative on the degree of burden. In many cases, this is because studies only looked at male patients.

Rogler & Hollingshead (1965) did examine gender difference in the degree of burden. They reported that schizophrenic illness in a wife had a more disruptive effect on the family than that in a husband. However, the study was carried out in the then rather traditional society of Puerto Rico and the findings have doubtful applicability to other cultures.

Few British studies have paid much attention to sex differences. Mandelbrote & Folkard (1961*a*,*b*) noted that, for male patients, there were more disturbed conjugal than parental families, this situation being reversed when the patient was female. In the study of depressed patients by Fadden and her colleagues (1987), wives were more isolated, possibly because they had fewer outlets to exploit when their spouse became mentally ill. It was also remarkable that wives often found it upsetting to have to take on traditionally male roles, even though they managed to do so competently. Such findings may have more general relevance and should perhaps be anticipated in the clinic.

Relatives' burdens in depressive disorder

The scant information about the specific effects of depression on the family of the patient has been recently reviewed elsewhere (Kuipers, 1987). It deals exclusively with the effects on spouses, although this may not be inappropriate as depressive patients are much more likely to be married and living with the marital partner than are people with schizophrenia. In these marriages there is frequently conflict (Hinchcliffe *et al*, 1978), particularly over role functions (Ovenstone, 1973*b*) and a high level of dependence (Birtchnell & Kennard, 1983). Fewer joint decisions are made with increasing pathology on the part of the husband (Collins *et al*, 1971), and the wives of depressive patients have significantly less independent social activity than controls (Nelson *et al*, 1970).

Fadden and her colleagues (1987) have recently conducted a pilot study of the spouses of persistently depressed patients of specified types, employing techniques of assessing burden developed in the more sophisticated studies of the effects of schizophrenia. Their findings show striking parallels with that work and emphasise the severity of the burden borne by spouses and the noticeably adverse effect upon their mental health.

Depression is not a minor problem for the community: the life-time expectancy of contacting a psychiatric hospital with depression may be as high as 11.9% for men and 20.2% for women (Sturt *et al*, 1984). Nor is it a problem which leads only to short periods of disability. In many cases the problem becomes a chronic one: Mann & Cree (1975) in a study of 'new long-stay' patients aged between 18 and 65 in hospitals found that affective psychosis accounted for 15.8% of patients and formed the largest single group after schizophrenia.

It is clear that more extensive study is required to establish the extent and prevalence of the burdens borne by the relatives of depressed patients.

Implications for further research and the provision of services

Although this review shows that there is now a large body of literature based on the systematic study of relatives' difficulties, much less is known of the best strategies for relatives to use in coping with their problems and of how, even if professionals knew what to advise, they could ensure that their advice was adopted. There is only experiential or anecdotal knowledge in these areas. In their review of research on burden, Kreisman & Joy (1974) describe the 'scatter-shot' approach on the part of researchers who have failed to follow through on promising leads in their own data: "This lack of sustained interest has left us with fundamental pieces of information missing". It must be said that, 13 years later, the situation remains very similar.

The results of this ignorance are likely to be considerable. It is apparent from the earlier studies on 'Expressed Emotion' (Brown *et al*, 1962, 1972; Vaughn & Leff, 1976) that the behaviour of relatives has a significant influence on the patient's likelihood of relapse with schizophrenia. This finding probably applies equally to depression (Vaughn & Leff, 1976; Hooley *et al*, 1986). While not all relatives behave in the same way, it is the nature of the burden placed on them that leads some to resort to ineffective strategies of coping. The intervention studies that have been reported (Liberman *et al*, 1981; Falloon *et al*, 1982; Leff *et al*, 1982; Barrowclough & Tarrier, 1984) and those now proceeding all adopt approaches that broadly aim to enhance the effectiveness of the relative's coping. The results confirm that improving the way relatives deal with the burdens of looking after a schizophrenic patient in the home has a beneficial effect on the course of the illness.

In addition to the indirect effects of burden on the patient's likelihood of relapse, there are direct effects upon the relatives' own mental health. This has been documented particularly for those married to depressed or neurotic partners (Kreitman, 1964;

Kreitman *et al*, 1970; Ovenstone, 1973*a*; Fadden *et al*, 1987) but has been noted for those living with schizophrenic patients (Brown *et al*, 1966; Hamilton & Hoenig, 1966, 1969; Stevens, 1972; Creer & Wing, 1974). The evidence inclines against an explanation in terms of assortative mating, at least in the groups studied.

Conclusion

A number of points can be drawn from this literature on the effects of psychiatric illness upon the families who live with the patient. A more widespread interest was shown in the topic in the late 1950s and early 1960s when community care programmes were first introduced. The first attempts to refine the measurement of burden in families also date from this time. Schizophrenic patients constitute the only group in which interest in family burden has been sustained, although there is evidence that families of other patient groups are also seriously affected by the patient's illness.

It is clear that families typically tolerate a great deal of difficult behaviour and that they frequently find the less clear-cut symptoms the most difficult to bear. They often lack knowledge about the nature of the patient's illness but receive little help from professionals in the management of difficult behaviour except in times of crisis. In spite of all this they rarely make complaints. Coping with their relatives' problems frequently results in adverse effects on their own health, both physical and psychological. From the first studies to the most recent, the point has been made repeatedly by those working in the area that relatives must not be asked to bear these burdens unassisted, and that they should be provided with more help from professionals. Recent studies describing interventions with families have shown that such help can be effective and worthwhile.

The intervention studies that have already been carried out have resulted in reduced relapse rates for schizophrenic patients, and this might also be a realistic aim for other diagnostic groups. A prerequisite of such intervention is knowledge of what problems are in fact faced by relatives. The need for further research is therefore clear.

The Psychological Well-being of Supporters of the Demented Elderly

J. M. EAGLES, A. CRAIG, F. RAWLINSON, D. B. RESTALL, J. A. G. BEATTIE and J. A. O. BESSON

Interviews were conducted with the co-resident supporters of 79 elderly subjects. Forty of these elderly subjects had been diagnosed as being demented (20 mildly, 12 moderately and eight severely) following psychiatric assessment. The supporters were screened for psychological well-being with the 60-item General Health Questionnaire (GHQ) and the Relatives' Stress Scale (RSS). Supporters of demented relatives showed significantly raised levels of stress on the RSS, but no increase in psychiatric morbidity on the GHQ, when compared with the supporters of non-demented relatives. The implications of these findings are discussed.

Community surveys (Kay *et al*, 1964; Parsons, 1965) have established that the great majority of demented elderly people are cared for at home. That is to say, the burden of caring for such patients falls specifically on those relatives and friends who attempt to support them in the community.

It has recently been suspected that these supporters of the demented elderly may be under considerable strain, and indeed they have been referred to as 'hidden patients' (Fengler & Goodrich, 1979). Studies of the families of the demented elderly (Grad & Sainsbury, 1965; Hoenig & Hamilton, 1969; Greene *et al*, 1982; Rabins *et al*, 1982; Gilleard, 1984; Gilleard *et al*, 1984) have found that the supporters experience high levels of stress and psychiatric disturbance. However, these studies have almost exclusively examined the families of patients referred to psychiatric services. As Grad (1971) and Gilleard *et al* (1984) have acknowledged, such patients and their families may be quite atypical of those in the community, and indeed may have been referred by their general practitioners *precisely on account* of the high levels of psychological stress within the family (Eagles *et al*, 1987).

Gilleard (1984) found that the supporters of patients attending a geriatric day hospital are less likely to be psychiatrically disturbed than the supporters of patients attending a psychogeriatric day hospital. This study apart, 'control' families have not been utilised in determining the effects of a demented person on his or her family; it is not known how much stress and psychological illness is precipitated by caring for a *non-demented* elderly relative.

The present study thus examined the psychological well-being of, and the strains perceived by, supporters of demented elderly subjects who had not been identified by referral to psychiatric services. It also investigated the same parameters in the supporters of a group of non-demented elderly subjects.

Method

The study was conducted in a general practice in Aberdeenshire. The practice has just over 14 000 patients of whom about half live in the town in which the practice is centred. The other patients reside in villages and in the country nearby.

A screening investigation of all subjects in the practice who were over 65 years of age had been carried out between August 1980 and April 1982. This survey has been described in more detail elsewhere (Eagles *et al*, 1987). A component of the screening investigation was the completion of the Mental Status Questionnaire (MSQ) as described by Kahn *et al* (1960) and by Wilson & Brass (1973). The MSQ consists of ten questions testing memory and orientation and it was answered by 1765 elderly subjects. Of this cohort, 205 scored 8 or less, indicating the possible presence of dementia. In order to investigate the follow-up validity of the MSQ (results of which will not be reported here) these 205 subjects were matched for age and sex with 205 subjects scoring 9 or 10 on the MSQ, both these groups of subjects being reinterviewed between September 1983 and May 1984. This interview was by a psychiatrist with experience in geriatric psychiatry (J.M.E. or F.R.) and included a repeat MSQ and the administration of the Orientation–Memory–Concentration Test (OMCT) described by Katzman *et al* (1983). This is an abbreviated, six-item version of the Information–Memory–Concentration Mental Status Test devised by Blessed *et al* (1968). The OMCT has the advantage that, unlike other brief screening tests for dementia, it has been positively correlated against cortical plaque counts at post mortem. The psychiatrist's interview, when possible and appropriate, included the gathering of information from relatives, and it concluded with the psychiatrist's assigning the subject to one of four categories: no dementia, mild dementia, moderate dementia or severe dementia.

For the present study, subjects who lived with an identifiable 'supporter' were selected. Supporters were asked, at the time of the psychiatrist's visit, whether they would be willing to receive a further visit from another doctor (A.C.), who would wish to discuss what problems, if any, they experienced in caring for their elderly relative. The first 80 supporters who agreed to this interview were included in the study. Since the order in which elderly subjects were visited depended only on their addresses it was likely that these 80 subjects comprised a fairly equal number of subjects whose 1980–1982 MSQ had been greater than 8 and whose 1980–1982 MSQ had been 8 or less. One supporter subsequently declined to participate on the day of A.C.'s visit. The interview of the supporter comprised:

1. *The 60-item General Health Questionnaire* (GHQ) (Goldberg 1972, 1978), a widely used instrument for the assessment of the presence and the degree of psychiatric morbidity.
2. *Relatives' Mood Scale* (RMS) (Greene *et al*, 1983). Supporters rated their mood on five symptoms—depressed, irritable, tired, tense and worried—using a 100 mm visual analogue scale, the ends of which were labelled 'not at all' and 'extremely'. A total mood score was represented by a mean of these five scores. Some supporters, particularly those who were elderly, found the concept of the visual analogue scale impossible to comprehend, and only 70 of the 79 supporters successfully completed the RMS.
3. *Relatives' Stress Scale* (RSS) (Greene *et al*, 1982). This is a 15-item scale designed to measure the stresses experienced by a relative who is caring for an elderly dependant in the community. The 15 questions relate to such topics as the effect the dependant is having on the relative's social life and mood state, and assesses negative feelings of the relative towards the dependant. Greene *et al* (1982) used a five-point scale of response to each question, but the present study simplified this to a three-point scale. Thus, a typical question reads: "Do you ever get depressed by the situation", and the possible responses were: (a) A great deal of the time, (b) Sometimes, (c) Never. The responses were then summated scoring 2 for the most 'stressed' response, 1 for the moderately 'stressed' response and 0 for the least 'stressed' response. The summation of these responses thus yielded a measure of the overall stress experienced by a supporter in caring for their elderly dependant.
4. *The Behaviour Rating Scale (BRS) of the Clifton Assessment Procedures for the Elderly (CAPE).* (Gilleard & Pattie, 1977). The BRS is an 18-item behaviour rating scale which is completed by an informant, and supporters rated the behaviour of their dependant with this instrument. Each item is rated on a three-point scale, and items cover a range of disturbed and/or dependent behaviour such as incontinence, immobility and night wandering. When the items are summated the total indicates the overall level of behavioural disturbance. The scale has been validated against outcome in elderly psychiatric patients (Pattie & Gilleard, 1978).

Thus, the supporter provided information concerning her psychological well-being (the GHQ and RMS), the stresses she experienced in caring for her elderly dependant (the RSS) and her assessment of the behavioural disturbance exhibited by her dependant (the BRS). In tandem with the data from the psychiatrist's assessments of the elderly subjects, these data from the supporters were analysed to address the principal question: does the presence, and the degree, of dementia affect the supporter's psychological well-being and/or the stresses she experiences in caring for her elderly dependant in the community.

Results

Of the 79 elderly subjects, 40 were male and 39 were female. Their mean age was 79.3 years (s.d. 6.5). The psychiatrist's ratings of the elderly subjects' mental state yielded the following:

No dementia	39
Mild dementia	20
Moderate dementia	12
Severe dementia	8

Thus, 39 subjects were adjudged to be non-demented and 40 to be demented, and these will be referred to as the 'non-demented group' and the 'demented group' respectively.

Of the 79 supporters interviewed, 21 were male and 58 female. Of these supporters, 41 were spouses, 25 were children, seven were siblings and six were a more distant relative or friend. Their mean age was 64.9 years (s.d. 13.9) with an age range of 22 to 88 years.

Table I shows the mean scores of supporters and dependents on each of the screening tests, grouped by the psychiatrist's ratings as to the presence and degree of dementia in the dependants.

Predictably, as global rating of dementia becomes more severe, the subjects perform more poorly on tests of cognitive function (MSQ and OMCT) and have higher levels of behavioural disturbance on the BRS of the CAPE.

The relationship between the mental state of the dependant and the psychological well-being of the supporter was investigated in two principal ways. Firstly the responses to the GHQ, the RMS and RSS were statistically compared for supporters of the demented group of dependants with those of the non-demented group of dependants. These comparisons were made by means of Mann-Whitney U Tests. The results are shown in Table II.

Supporters of demented and of non-demented dependants do not differ significantly in their scores on the 60-item GHQ. The two groups of supporters do differ at a highly significant level in their scores on the RSS ($P<0.001$) and there is a trend towards their scores differing on the RMS ($P<0.1$).

Since dementia increases in prevalence with increasing age it was possible that the 'demented group' would be significantly older than the non-demented group, and that this increased age and resultant infirmity itself, rather than the presence of dementia, might affect the well-being of the supporters of the demented group. The mean age of the demented group was 79.8 years (s.d. 6.4) and that of the non-demented group was 78.7 years (s.d. 6.7). These groups

TABLE I

Dependants' and supporters' mean scores on screening tests by psychiatrist's global rating of dependant (Standard deviations in parentheses)

	All patients ($n=80$)	*No dementia ($n=39$)*	*Mild dementia ($n=20$)*	*Moderate dementia ($n=12$)*	*Severe dementia ($n=8$)*
Dependants	7.18	9.13	7.30	4.50	1.38
MSQ	(2.85)	(0.95)	(1.81)	(1.38)	(1.19)
OMCT	17.15	24.08	14.55	9.08	2.00
	(8.66)	(4.23)	(4.30)	(3.66)	(2.51)
BRS	7.05	3.80	7.50	11.58	15.00
	(5.90)	(3.56)	(4.43)	(6.24)	(6.14)
GHQ	3.85	3.62	2.95	5.25	5.13
Supporters	(6.51)	(5.74)	(4.38)	(11.10)	(6.29)
Mood scale	16.14	12.63	14.61	26.82	21.67
	(18.76)	(17.00)	(13.27)	(26.11)	(23.40)
Stress scale	4.94	2.69	5.50	7.50	10.63
	(5.54)	(3.34)	(5.86)	(6.36)	(6.84)

did not differ significantly when compared by means of a *t*-test ($F=1.08$, $t=0.79$, NS). Furthermore, the correlation between the age of the dependants and the RSS score of their supporters did not reach statistical significance ($\tau=0.098$, NS).

The relationship between supporters' psychological well-being and the *severity* of the dependants' dementia was investigated by comparisons of the groups of dependants arising from the psychiatrist's global ratings as to the presence and severity of dementia. The elderly subjects were grouped as: no dementia ($n=39$), mild dementia ($n=20$), and moderate/severe dementia ($n=20$). Mann-Whitney U Tests were carried out to investigate differences in the supporters' scores on the GHQ, RMS and RSS between supporters of the non-demented group, the mildly demented group, and the moderately/severely demented group.

These analyses showed that, for the three groups of dependants (no dementia, mild dementia, moderate/severe dementia):

1. *GHQ*: there were no significant differences in GHQ scores between the three groups of supporters.
2. *RMS*: the supporters of the mildly demented groups did not differ significantly from those of the other two groups. There was a trend ($P<0.1$) towards the moderately/severely demented group's supporters scoring more highly than those of the non-demented group.
3. *RSS*: there were trends ($P<0.1$) towards differences in the scores of the supporters of the mildly demented group and those of the other two groups in the expected directions. The supporters of the non-demented group had very significantly lower scores ($P<0.001$) than those of the moderately/severely demented group.

The second principal means of testing the relationship between the supporters' psychological well-being and the disability of their dependant was by the calculation of correlation coefficients (Kendall's τ) between the supporters' scores on the GHQ, RMS and RSS and the dependants' scores on the Mental Status Questionnaire (MSQ), the Orientation–Memory–Concentration Test (OMCT) and on the Behaviour Rating Scale (BRS) of the CAPE. The results of these analyses are shown in Table III.

Neither the supporters' GHQ scores nor their RMS scores correlates significantly with the two measures of cognitive impairment in the dependants, the MSQ and the OMCT. The supporters' scores on the RSS however, correlate at a highly significant level ($P<0.001$) with measures of the dependants' cognitive impairment (MSQ and OMCT) and with their level of behavioural disturbance as rated on the

BRS of the CAPE. The dependants' BRS scores are also significantly correlated with the supporters' scores on the RMS and on the GHQ. It should be noted that the BRS scores derive from the supporters' (subjective) appraisal of their dependants' behaviour. Thus, psychological morbidity and/or strain in the supporters may result in their rating their dependants' behaviour as more disturbed on the BRS, rather than the morbidity and strain necessarily resulting from the dependants' disturbed behaviour.

The scores of supporters on the RSS did not appear to be independent of their psychiatric morbidity, as measured by the GHQ and RMS scores. Correlation coefficients (Kendall's τ) between the supporters' scores on the three scales were as follows:

RSS with GHQ, $\tau=0.34$
RSS with RMS, $\tau=0.34$
GHQ with RMS, $\tau=0.44$.

All these correlations are highly statistically significant ($P<0.001$).

The two relatively large groups of supporters i.e. spouses ($n=41$) and children ($n=25$), were compared for differences in their levels of psychological morbidity and strain by comparisons of their scores on the GHQ, RMS and RSS with Mann-Whitney U tests. No statistically significant difference was found between these two groups of supporters on any of the three scales.

Discussion

This study has shown that the co-resident supporters of elderly demented patients experience a significantly increased degree of stress, as measured by the RSS, when compared to relatives living with a non-demented old person. The stress experienced escalated significantly with increasing severity of dementia in the elderly dependants. There was no hard evidence, on the other hand, that psychiatric morbidity in the supporter (as measured by the 60-item GHQ) was influenced either by the presence or by the severity of dementia in the elderly dependant. While this finding accords with those of Eagles *et al* (1987), other researchers have almost universally found high levels of psychiatric morbidity in supporters of the demented elderly (Grad & Sainsbury, 1965; Hoenig & Hamilton, 1969; Greene *et al*, 1982; Rabins *et al*, 1982; Gilleard, 1984; Gilleard *et al*, 1984).

The possible reasons for the discrepancy in these findings has been discussed elsewhere (Eagles *et al*, 1987), and will be only briefly rehearsed here. One of the most probable explanations is that of sampling bias. Other studies into the psychiatric well-being of the supporters of demented relatives have investigated families in which the demented person has been the subject of psychiatric referral. These patients may have been selected by the primary care team for psychiatric referral as a direct result of the relatives' psychiatric morbidity, while patients whose families 'cope' without becoming psychiatrically unwell may not be referred to psychiatrists at all.

It is possible that the people of Aberdeenshire are atypical of other areas of the UK. This is partly supported by the finding of Gilhooley (1984), that none of the relatives caring for 37 demented attenders at an Aberdeen Day Hospital had serious psychiatric morbidity. The area in which the present study was based has a high degree of community cohesiveness, and many supporters seemed remarkably stoical and uncomplaining about their caring for a demented relative. Jolley & Arie (1978) summarised one of the major current problems in community care of the elderly when they stated that: "Better standards of living and expectations of the 'good life' do not accord well with caring for a persistently disturbed relative". Perhaps these raised expectations have not yet percolated through to the 'old fashioned' inhabitants of semi-rural Aberdeenshire.

It is interesting to note that the high scores of supporters of demented relatives on the RSS did not 'spill over' into significantly raised scores on the 60-item GHQ. This might be related to the geographical stability and community cohesiveness of the area, making it more likely that the supporters would themselves be visited and supported, a factor which Zarit *et al* (1980) showed to have the effect of relieving supporters' feelings of 'burden'.

On the other hand, the failure to establish a relationship between caring for a demented relative and psychiatric morbidity on the GHQ may indicate that this instrument is inefficient in detecting psychiatric morbidity in the elderly. This possibility is partly borne out by the fact that a weak relationship *was* found between caring for a demented relative and the supporters' scores on the RMS, a very brief and relatively unrefined instrument which many elderly supporters did not fully comprehend. Benjamin *et al* (1982) and Goodchild & Duncan-Jones (1985) have recently drawn attention to the somewhat anomalous GHQ response category 'No more than usual'. These authors argue that for items describing pathology, this response can indicate chronic illness rather than good health, and this may be a particularly cogent criticism in evaluating the responses of elderly people who have been caring for a demented relative over a lengthy period of time.

Correlations of supporters' levels of strain and psychiatric morbidity with their dependants' scores on the CAPE were higher than the correlations with dependants' scores of cognitive impairment on the MSQ and OMCT. While the supporters' rating of their dependants' behaviour on the CAPE is unlikely to be independent of their own feelings of strain and distress, it is not surprising that behavioural disturbance rather than cognitive impairment *per se* appears to give rise to psychiatric morbidity. Indeed, this mirrors the findings of Isaacs *et al* (1972) who, investigating the families of geriatric medical referrals, found that relatives did not suffer 'undue strain' on account of their dependants' confusion *per se*, but that strain did arise from concomitant behavioural disturbances. Other studies (Sanford, 1975; Gilleard *et al*, 1982; Greene *et al*, 1982; Rabins *et al*, 1982) have established that there are specific behavioural problems (e.g. night-time wandering, incontinence, violence and apathy), which supporters find particularly stressful and difficult to tolerate in their elderly dependants.

The findings of this study have service implications. Given that the great majority of the supporters of the demented elderly are 'stressed' rather than psychiatrically disturbed, psychiatrists do not require to become involved with these families. The task of 'supporting the supporters' can appropriately be left in the hands of the voluntary agencies and primary care teams.

The present study indicates that supporting a demented relative who has not been 'selected' by referral to psychiatric services does incur a considerable strain on relatives, but does not in itself lead to increased rates of psychiatric morbidity as measured by the General Health Questionnaire. While this requires to be confirmed in other parts of the country, and while there are doubts about the utility of the GHQ in an elderly population under chronic stress, this evidence suggests that psychiatric screening of these relatives would not be a productive venture. It is worth emphasising that this finding does not diminish the need to provide community support for relatives who are attempting to cope with a demented elderly dependant. Indeed it is quite possible that it is this very support, which is well co-ordinated in the general practice studied, that prevents the transition of relatives from 'stress' to overt psychiatric illness.

Acknowledgements

The authors wish to thank Dr Chris Gilleard for his valuable comments on this paper and Miss Sybil McLeod for her collation and processing of the data. This project was supported by a grant from Grampian Health Board. While carrying out this research, Dr Craig's post was funded by the Scottish Home and Health Department.

Schizophrenia therapy: the importance of balance

Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets this critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.[1]

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,[2-5] and because injections need only be given every four weeks, patients hardly know they are being treated.

Piportil
DEPOT PIPOTHIAZINE PALMITATE

Piportil Depot Prescribing Information
Dosage: *(Adults)* Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg (1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, severe cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, depression, blurred vision, asthenia, impotence, dry mouth, nausea, amenorrhoea, galactorrhoea, hypotension, hyperhydrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08½ ampoules (PL0012/0117). **References:** 1. A SCHIZOPHRENIC.

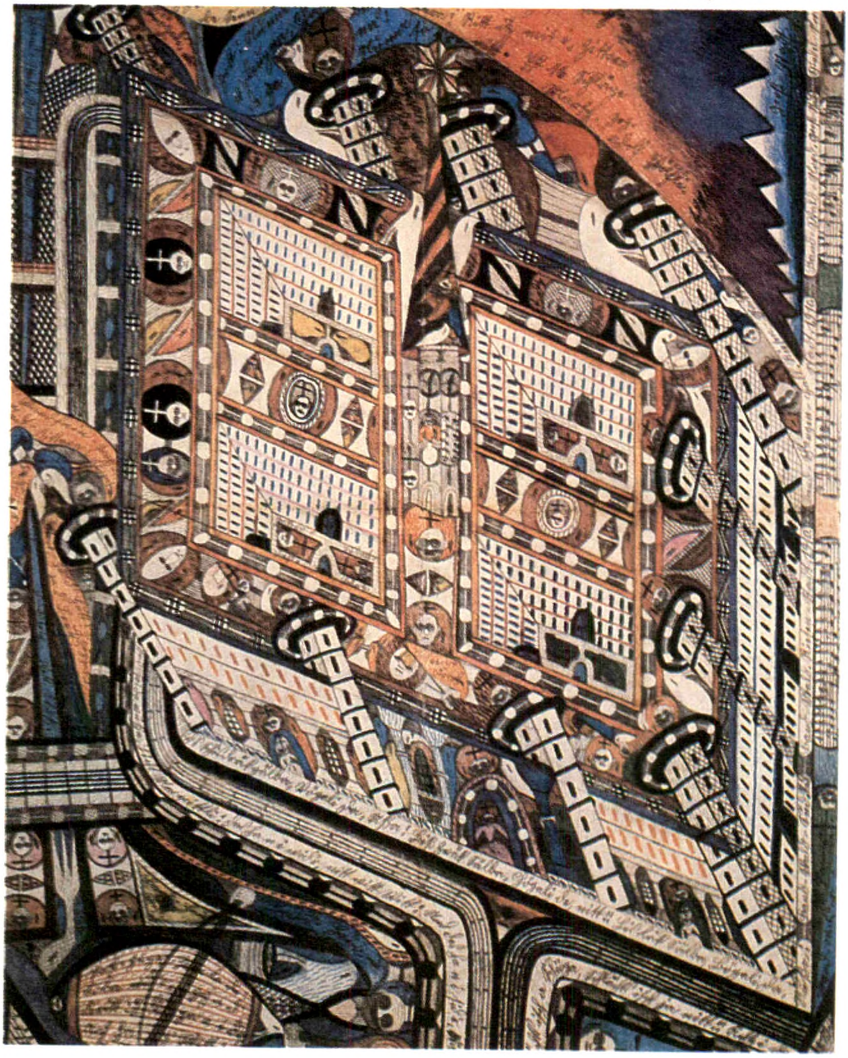
Adolf Wölfli spent 35 years in the Waldau Mental Hospital, Berne, suffering from schizophrenia. During that time he produced many drawings that have since gained widespread acclaim.

The picture below is one of a number that, we believe, give an insight into the schizophrenic mind and is reproduced with the kind permission of the Museum of Fine Art, Berne.



A SOLUTION.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol it has become widely established throughout the world as an effective antipsychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration following a single deep intramuscular injection.

Dosage is from 50–100mg in mild symptomatology whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation and a reduced requirement for antiparkinsonian medication, leaving him better able to participate in other forms of therapy.

100mg/ml

HALDOL*

haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

▼**Presentation**: Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses**: As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side-effects, precautions, contra-indications**: Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa, and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side Effects: In common with all neuroleptics, the following side effects may be observed: sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Rarely neuroleptic malignant syndrome has been reported. **Dosage**: Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. Dosage should be individually determined. As a guide: in mild symptomatology and in the elderly 50-100mg every 4 weeks; in moderate symptomatology 100-200mg every 4 weeks; in severe symptomatology 200-300mg or more every 4 weeks. **Product Licence No**: PL0242/0095, PL0242/0094 **Basic NHS Cost**: 100mg/ml: 1ml x 5 £24.00; 50mg/ml: 1ml x 5 £15.60 (correct at time of printing). Further information is available on request from **Janssen Pharmaceutical Limited**, Grove, Wantage, Oxon OX12 0DQ.

PRESCRIBING INFORMATION

Depixol Injection and Depixol-Conc. Injection *contain cis(Z)-flupenthixol decanoate, 20mg per ml and 100mg per ml respectively, in thin vegetable oil.*

Indications *Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy.*

Dosage and Administration *By deep intramuscular injection, 1-2ml every 2-4 weeks, to a maximum of 400 mg weekly. Children: Not recommended for children.*

Side Effects *Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson drug treatment.*

Contra-indications *Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusional, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy.*

Further Information *Overdosage should be treated: (a) by anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur, (b) by sedation (with benzodiazepines) in the unlikely event of agitation or excitement, (c) by noradrenaline in saline intravenous drip if the patient is shocked.*

Package Quantities & Basic NHS Prices *Boxes of 10 x 20mg (1ml) £15.53, 10 x 40mg (2ml) £25.99, 10 x 100mg (1ml) ampoules £59.53, 5 x 20mg and 5 x 40mg syringes £8.51 and £13.74, 1 x 200mg (10ml) and 1 x 500mg (5ml) vials £14.74 and £28.27.*

The Mental Health of Elderly Couples

I. The Effects of a Cognitively Impaired Spouse

J. M. EAGLES, J. A. G. BEATTIE, G. W. BLACKWOOD, D. B. RESTALL and G. W. ASHCROFT

In a general practice population, 274 elderly married couples completed the Mental Status Questionnaire (MSQ), the 60-item General Health Questionnaire (GHQ) and the Leeds General Scales for the Self-assessment of Depression and Anxiety. The only relationship detected between cognitive impairment on the MSQ and psychiatric morbidity in the partner was a fairly weak negative correlation between the wives' MSQ and the Leeds Depression score of their husbands. These findings differ from those of previous studies, which have found high rates of psychiatric morbidity in the relatives of demented patients, and the possible reasons for these differences are discussed. Most importantly, other studies have involved the relatives of patients referred to psychiatric services, and these families may be quite different from those in which the demented relative is not referred to a psychiatrist.

In the elderly living at home, the high prevalence rate of dementia is well documented (Kay *et al*, 1964*a*; Parsons, 1965; Bollerup, 1975). The great majority of demented patients are cared for in the community (Kay *et al*, 1964*a*) a situation which is likely to continue and one which will inevitably lead to the main responsibility for their care continuing to fall upon the families of such patients.

It is well recognised that the viability of family support systems is a major determinant of whether or not a demented old person remains in the community (Bergmann *et al*, 1978; Greene & Timbury, 1979). Changes in the age structure of the population are altering the character of such family support systems in that the supporters themselves are tending to become increasingly elderly (Isaacs *et al*, 1972), and it is likely that the more elderly supporters will be those for whom coping with a demented relative will be most difficult. It is thus important to study these elderly supporters in the hope of establishing how their ability to cope might be optimised, for example by attempting to enhance their informal social support network (Zarit *et al*, 1980).

Studies of the stresses involved in caring for an elderly psychiatrically disturbed patient have found these to be considerable (Grad & Sainsbury, 1965; Hoenig & Hamilton, 1969; Gilleard *et al*, 1984). These studies, however, have examined the families of patients referred to psychiatric services, who may be unrepresentative of the families of all elderly people with psychiatric illnesses.

The present study utilised the data from a screening investigation of all those aged over 65 in a general practice population. It was thus possible to examine the psychological well-being of the spouses of an unselected group of cognitively impaired old couples.

Method

The study was conducted in a general practice in Aberdeenshire. The practice has about 14 000 patients of whom about half live in the town in which the practice is centred. The other patients live in smaller towns, in villages, and in the country nearby.

All patients registered with the general practice who were aged 65 and over on the 1 April 1981 constituted the base population for the survey. They numbered 1794 in total. Of these, 16 were unable or unwilling to participate, leaving a total of 1778 subjects who completed the assessment (99.1% of the initial cohort). The subjects were visited by a research worker at their place of residence between August 1980 and April 1982. Interviews were conducted on 1528 of the subjects by a district nurse in the practice and the remaining 250 assessments were carried out by one of two senior medical students. After division of the practice into 13 geographically smaller areas, the subjects were divided by sex and then visited in random order. This was done to avoid the possible 'contaminating' effect of interviewing one neighbour or relative immediately after the other.

At the time of interview the living group of the subject was ascertained in terms of whether they lived alone, with their spouse, or with other relatives. In order to identify all the opposite sexed 'pairs' who lived together and who were both included in the survey population, the lists of subjects visited were scrutinised for males and females of the same name living at the same address. Where households were identified in which there were three or more people of the same name, these households were considered not to contain any 'pairs' for inclusion in the study. The remaining 'pairs' were cross-checked with the information on their living group, and included only if each member of the pair was recorded as living with a spouse. Of the 1778 subjects assessed, 548 were established by this method as living as one of a married couple, of whom both were over 65 and both had been assessed in the course of the survey.

In the context of a comprehensive screening interview, other components of which have been described elsewhere (Restall, 1984), all subjects were tested for cognitive impairment with the Mental Status Questionnaire (MSQ). This is the British version of a questionnaire first developed by Kahn *et al* (1960), consisting of ten questions testing memory and orientation. The MSQ score has been shown by Wilson & Brass (1973) to correlate quite highly ($r = 0.82$) with an independent rating of the presence and degree of dementia in elderly patients. In the study of Wilson & Brass (1973) the mean score of patients considered to have 'mild dementia' was 7.84, and one may thus consider a score of 8 or less to indicate the likely presence of dementia.

Subjects also completed the 60-item General Health Questionnaire (GHQ) (Goldberg, 1972, 1978). The GHQ has been widely used as a screening tool for detecting psychiatric morbidity in the community. It is also of use in comparing different populations, by employing either the proportions of high scorers or differences in mean scores (Goldberg, 1978; Tarnopolsky *et al*, 1979). Of the 548 subjects constituting one of a married couple, 546 completed the GHQ successfully. The other two subjects were considered by the interviewer to be too demented, even with assistance, to complete it satisfactorily.

In the first 300 of the screening interviews, mood was self-rated by visual analogue scale, but many of the elderly subjects had difficulty in grasping the concept of this scale. It was thus abandoned and the subsequent interviewees completed the Leeds General Scales for the Self-assessment of Depression and Anxiety (Snaith *et al*, 1976). These scales constitute a development of the Wakefield Self-assessment of Depression Inventory (Snaith *et al*, 1971), and have been shown to correlate highly with observer rated depression and anxiety (Snaith *et al*, 1976). A total of 453 of the 548 spouses completed both of these scales.

Three methods were adopted to investigate the relationship between cognitive impairment in one member of a couple and the psychological well-being of the other.

(1) Correlation coefficients (Kendall's τ) were calculated between the MSQ scores for the subjects of each sex and the scores on the GHQ and Leeds scales of their spouse.

(2) Those subjects scoring 8 or less on the MSQ were identified, such subjects constituting a 'demented' group. They were matched with a 'non-demented' group who scored 9 or 10 on the MSQ. The matching was done by a rater who was blind to the purpose of the study. She identified 'non-demented' controls matched for age and sex with each 'demented' subject and then identified the spouse of these 'non-demented' controls who was most closely matched in age with the spouse of the 'demented' subject. A married couple, of whom neither was demented, was thus identified as being the most accurate match of a couple in whom one of the partners was demented. Comparisons of the scores on the GHQ and Leeds scales of the spouses of the 'demented' and 'non-demented' subjects in these groups should thus provide accurate information about the effects of living with a demented individual.

(3) Subjects were divided into those scoring 8 or less on the MSQ ('demented group') and those scoring 9 or 10 on the MSQ. The frequency of 'caseness' on the GHQ and Leeds scales was then compared between the spouses of 'demented' subjects and the spouses in all the couples in which neither spouse was demented. 'Demented' subjects themselves, although they lived with a non-demented spouse, were excluded from this analysis since dementia may contaminate responses to the GHQ and Leeds scales.

Results

The characteristics of the total cohort's scores on the MSQ, GHQ and Leeds scales were as follows:

Mental Status Questionnaire

All 548 subjects completed the MSQ. Their mean score was 9.65 (s.d. 0.82). Thirty-one subjects (5.7% of the total sample) scored 8 or less, these subjects constituting the 'demented' group.

General Health Questionnaire (60-item)

This was completed by 546 of the subjects. Their mean score was 3.46 (s.d. 6.41). It is usual to take a health/illness cut-off score of 11/12 in the 60-item GHQ, and 51 subjects (9.3%) scored 12 or more.

Leeds General Depression Scale

This was completed by 453 of the subjects. Their mean score was 2.09 (s.d. 2.64). The advised health/illness cut-off score is 6/7 (Snaith *et al*, 1976) and 37 subjects (8.2%) scored 7 or more.

Leeds General Anxiety Scale

This was completed by 453 of the subjects. Their mean score was 1.83 (s.d. 2.81). The advised health/illness cut-off score is again 6/7, and 44 subjects (9.8%) scored 7 or more.

The mean age of all 548 subjects was 73.0 (s.d. 5.1). The mean age of the 31 'demented' subjects was 76.7 (s.d. 7.3). In comparison with the 'non-demented' subjects by means of a Mann-Whitney U Test, the demented subjects were, predictably, significantly older ($z = 2.81$, $P < 0.005$). Of the 31 'demented' subjects, 20 were male and 11 were female.

The correlation coefficients between the MSQ scores of the subjects of each sex and the spouses' GHQ and Leeds Scales scores are shown in Table I. The number of pairs involved in each analysis is shown in brackets.

If cognitive impairment were associated with psychological disturbance in the subject's living partner, a significant negative correlation between the MSQ scores and the partners' scores on the GHQ and Leeds Scales would have been expected. As Table I shows, this

TABLE I

Correlation coefficients (Kendall's τ) between scores on Mental Status Questionnaire and spouses' scores on General Health Questionnaire, Leeds Depression and Leeds Anxiety Scales

	Spouse's GHQ	*Spouse's Leeds Depression*	*Spouse's Leeds Anxiety*
Male MSQ	−0.032 (274 pairs)	0.042 (227 pairs)	0.083 (227 pairs)
Female MSQ	−0.004 (272 pairs)	−0.129* (224 pairs)	−0.051 (224 pairs)

*$P<0.02$

relationship was detected only between the wives' MSQ and their husbands' scores on the Leeds Depression scale.

The scores on the GHQ and Leeds Scales of the spouses of the 31 'demented' subjects (MSQ 8 or less) and the spouses of the matched 'non-demented' subjects (MSQ 9 or 10) are shown in Table II.

TABLE II

Scores of the spouses of 'demented' and 'non-demented' subjects on the 60-item GHQ and Leeds Scales

	Mean score on GHQ (31 sets of paired data)	*Mean score on Leeds Depression Scale (28 sets of paired data)*	*Mean score on Leeds Anxiety Scale (28 sets of paired data)*
Spouses of demented subjects	3.13 (s.d. 4.51)	2.29 (s.d. 2.62)	1.50 (s.d. 1.67)
Spouses of non-demented subjects	4.48 (s.d. 6.34)	2.04 (s.d. 2.30)	1.57 (s.d. 2.24)

The spouses of the demented subjects thus show a slightly higher mean score on the Leeds Depression Scale, while the spouses of the *non-demented* subjects have higher scores on the GHQ and Leeds Anxiety Scale. Comparison of the scores of the two groups of partners with the Wilcoxon matched-pairs signed-ranks test showed no significant differences for their scores on any of the three scales.

The frequency of 'caseness' on the three scales was compared in the spouses of the 31 'demented' subjects against all the spouses of non-demented subjects, excluding the 31 'demented' subjects themselves. 'Cases' were defined as scoring 12 or more on the GHQ, and as scoring 7 or more on the Leeds Scales. The frequency of 'cases' in the two groups is shown in Table III.

Analysis of differences in the rates of 'caseness' between the two groups, by means of χ^2 tests, found there to be no significant differences on any of the three scales.

TABLE III

Frequency of 'cases' in the partners of demented subjects and in all partners of non-demented subjects

	Cases on GHQ	*Cases on Leeds Depression Scale*	*Cases on Leeds Anxiety Scale*
Spouses of demented subjects	3/31 (9.7%)	3/28 (10.7%)	0/28 (0%)
Spouses of non-demented subjects	49/574 (8.5%)	35/476 (7.4%)	45/476 (9.5%)

Discussion

Data from 274 elderly married couples were analysed to investigate whether a relationship existed between cognitive impairment in one partner and psychological distress or disturbance in the other. Three methods of analysis were employed, but the only such relationship detected was a relationship between wives' impairment on the MSQ and husbands' scores on the Leeds Depression Scale.

The scale of this relationship is surprisingly small, not only at a 'common sense' level, but also in comparison with previous studies in the same area. The study of Gilleard *et al* (1984) investigated the supporters of over 200 elderly patients who attended geriatric or psychogeriatric day hospitals in the Edinburgh area, the majority of these patients being demented. Of the supporters, 67% scored as 'cases' on the 30-item GHQ. Using a global rating scale, Grad & Sainsbury (1965) considered 40% of the families of elderly patients referred to psychiatric services in Chichester and Salisbury to be suffering 'severe burden'. Other authors, without feeling the need for formal testing, have commented on the high levels of psychological distress in such families (e.g. Bergmann *et al*, 1978; Greene & Timbury, 1979). The only study which appears to support the present findings is that of Gilhooly (1984). She studied 37 supporters of demented attenders at Aberdeen day hospitals and found that the majority of supporters were well or only 'mildly mentally impaired'.

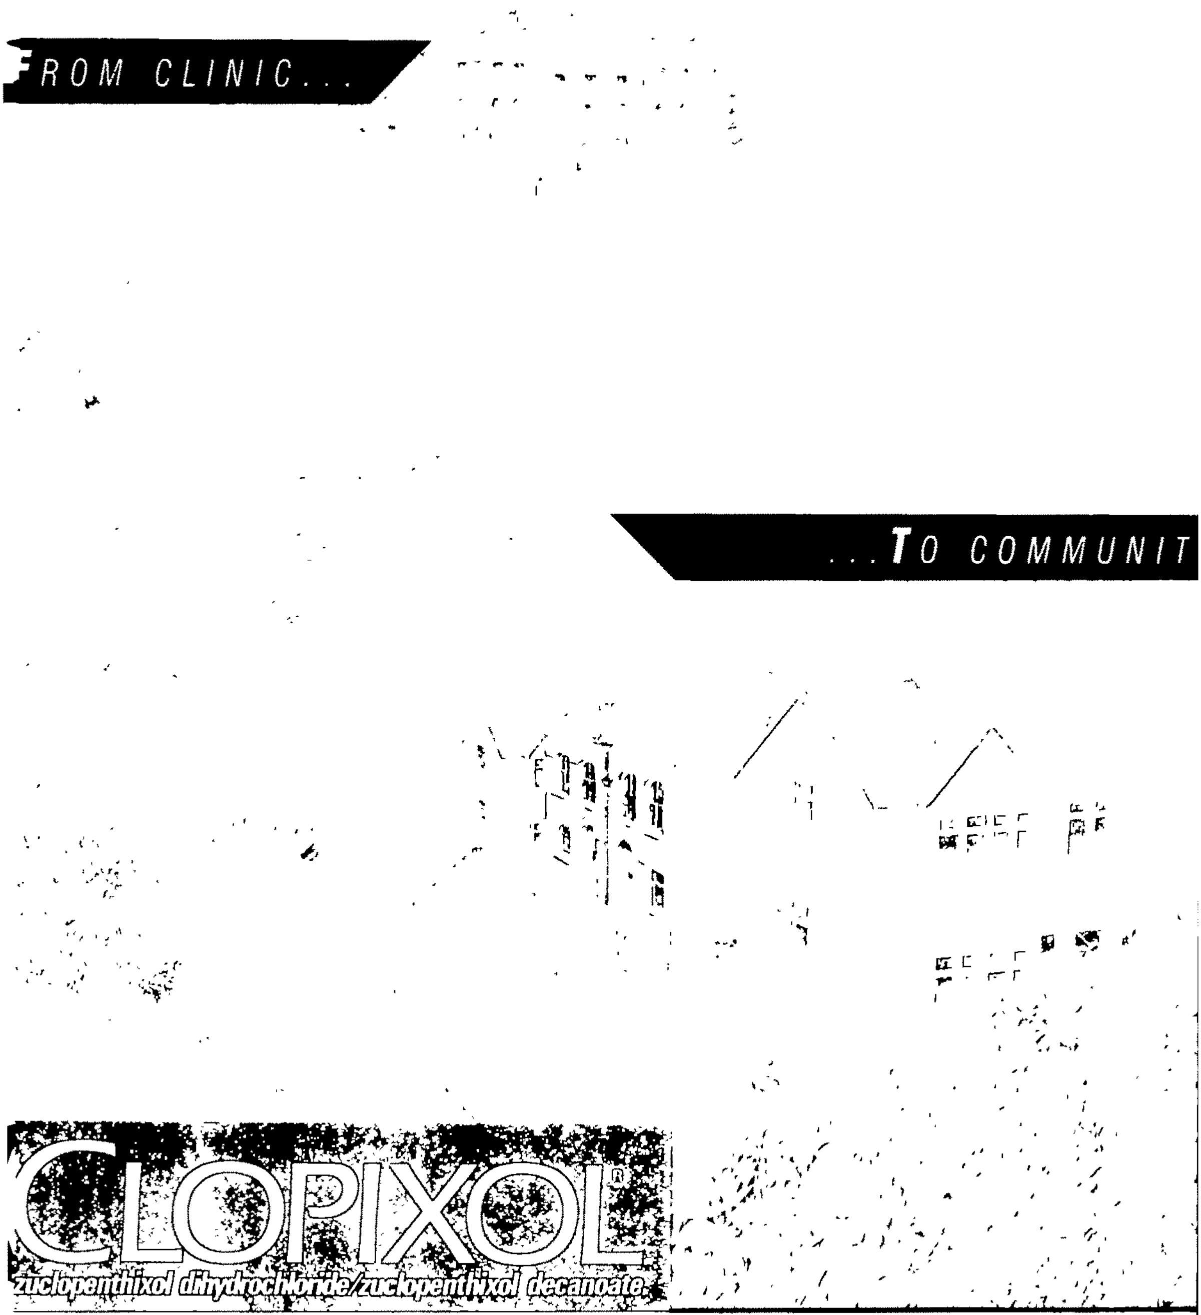
All the studies quoted above, however, share the disadvantage of their being based on the families of elderly patients who have been referred to psychiatric services. Such a referral from the general practitioner may often arise, indeed it may usually arise, not on account of the patient's dementia, but on account of the stresses and psychological disturbances arising in the family as a result of this dementia. Clearly then, studies on the levels of psychological disturbance in such a population of supporters must take into account the fact that the patients may have been 'selected' on account of that self-same disturbance in the relatives.

A weakness of the present study is the diagnosis of 'dementia' on the basis of the Mental Status Questionnaire. The illness/health cut-off point of 8/9 will undoubtedly lead to false negative and false positive classifications. The study of Wilson & Brass (1973), however, showed that a cut-off score of 8/9 would result in more false negatives than false positives. Also, the overall prevalence of dementia with this cut-off point (5.7%) is lower than most estimates of the community prevalence of dementia (e.g. Nielsen, 1962; Kay *et al*, 1964*a*; Williamson *et al*, 1964; Hagnell, 1970), suggesting that a relatively conservative number of 'demented' individuals may have been so classified. However, as well as including a small number of normal old people in the 'demented' group, this will include a relatively large number of individuals with dementia of only mild severity. It may be that supporters develop psychological distress only when their dependant becomes more severely demented, and that this factor may explain the discrepancy between the present study and those quoted above. With this possibility in mind, we compared the partners of patients scoring 6 or less on the MSQ ($n = 10$) with their matched control partners. This comparison was repeated for the partners of the 15 patients scoring 7 or less on the MSQ, this being the point on the 'American MSQ' at which Reisberg *et al* (1982) consider patients usually suffer from 'moderate cognitive decline'. While the groups were admittedly very small, these comparisons between the partners of more severely demented and of normal subjects did not reveal any significant differences in scores on the GHQ and Leeds Scales. Zarit *et al* (1980) also found no relationship between the severity of dementia and the psychological well-being of the supporter.

In diagnosing 'dementia' as we did in the present study, the MSQ has the further disadvantage of measuring only memory and orientation. Other aspects of cognitive decline are not measured and of course there is no account taken of changes in behaviour and personality. While simple decline in memory (as measured by the MSQ) may be quite easily tolerated by relatives, behavioural deterioration is much more stressful (Sanford, 1975; Gilleard *et al*, 1982). Thus, the present study's 'demented' group may be significantly less disturbed behaviourally than those who are referred to psychiatric services and who have comprised the subjects for previous studies on supporters' psychological well-being.

It is also possible that the differences between the findings of this study and those of others arise as a result of special characteristics of the area and the people investigated. The present study found that only 9.3% of the 548 subjects constituted a 'case' on the 60-item GHQ, this rate of 'caseness' being considerably lower than the rate of 30% found in a community sample of women in Dundee by Hobbs *et al* (1983) or the 25% found by Benjamin *et al* (1982) in Manchester. Both of these studies were of younger populations, and the lower rates in our sample may reflect the fact that neuroses become less common with increasing age (Kay, 1976; Post, 1982). That being said, the rates of 'caseness' in the present study are lower than those for neurotic illness found by the community studies of the elderly in Newcastle (Kay *et al*, 1964*a*; Bergmann, 1971). These discrepancies may be partly accounted for by semi-rural/urban differences, and there is certainly evidence that younger patients in rural communities tend to be psychologically healthier than their urban counterparts (Brown & Harris, 1978; Dilling & Weyerer, 1984). The particular area studied is also of low geographical mobility, high community cohesiveness and has a high standard of primary medical care. These factors may predispose to a generally low level of psychiatric morbidity and an increased resilience to stress, notably to the stress of caring for an elderly demented relative. It is possible that the primary care team is identifying stressed relatives at an early stage and is invoking supportive and/or pharmacological measures to alleviate the stress and to prevent or treat overt psychiatric morbidity.

Our results may reflect the fact that the GHQ and Leeds scales are unsuitable screening instruments when seeking to detect psychiatric morbidity in an elderly population. The Leeds scales have not, to the authors' knowledge, been validated in community samples, but the GHQ has been on several occasions (e.g. Goldberg & Blackwell, 1970; Tarnopolsky *et al*, 1979; Benjamin *et al*, 1982; Hobbs *et al*, 1983). While doubts have been expressed about the GHQ's sensitivity as a screening instrument for psychiatric morbidity (Benjamin *et al*, 1982), especially in subjects under chronic stress (Finlay-Jones & Murphy, 1979), it has been validated satisfactorily against psychiatric interview in the supporters of elderly day hospital attenders (Gilleard, 1984; Gilleard *et al*, 1984). However, validation of the



CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride
Indications Psychoses
Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses
Children Not recommended
Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs
Contraindications Acute alcohol, barbiturate or opiate poisoning Intolerance to other neuroleptics Pregnancy (relative) Use with caution in patients with Parkinsonism, severe arteriosclerosis, senile confusion states, serious renal, hepatic or cardiovascular disease
Overdosage Overdosage should be treated by gastric lavage
Package quantities and NHS price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3 05, bottles of 100 Clopixol Tablets 10mg £7 50, bottles of 100 Clopixol Tablets 25mg £15 00 PL Nos 0458/0027,0028,0029 PA Nos 115/5/3,4,6
CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil
Indications Psychoses, especially schizophrenia
Dosage and Administration 200 500mg every 2-4 weeks by deep intramuscular injection
Children Not recommended
Side-effects Early (frequent) and late tardive dyskinesias Extrapyramidal effects sometimes require dose reduction or anti Parkinson treatment
Contraindications Comatose states
Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease Parkinson's disease, pregnancy car dr[illegible] or machine operation
Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur (b) sedation (with benzodiazepines) in the unlikely event of agitation or excitement [illegible] intravenous drip if the patient is [illegible]
Package quantities & NHS price [illegible] of printing) 10 x 200mg (1ml) ampoules £[illegible] 1 x 200mg (10ml) vial £28 63, 5 x [illegible] ampoules £36 23 PL Nos 0458 [illegible] PA Nos 115 5 1 5 7

Stress related diseases account for a substantial proportion of working days lost.

Stress may manifest itself directly as psychological symptoms such as anxiety or depression or it may act as a contributing factor in the development of physical illness. All too often the sufferer turns to self medication with alcohol, or is prescribed tranquillising drugs on a long term basis.

Stress is a normal part of most peoples lives and if they are to remain well they need to develop techniques for dealing with it before it produces physical or psychological damage.

St. Andrew's Hospital provides treatment for a wide range of stress related disorders such as anxiety states, phobic conditions, eating disorders and problems of substance abuse. The treatment programme includes anxiety management, relaxation techniques, cognitive therapy, social skills training and problem solving groups.

The hospital is set in 100 acres of parkland and offers a wide range of sporting and recreational facilities so that patients are able to improve their physical as well as their mental health.

GHQ in a community sample of elderly people has not yet been carried out.

The present study found a significant association between depression in husbands and cognitive impairment in the wives, but the reverse relationship did not apply. This finding is at odds with other studies (Gilhooly, 1984; Gilleard *et al*, 1984) which found higher levels of distress in females than in male supporters. The supporters in these studies differed from our supporters by being younger, by less often being spouses and by being in contact with psychiatric services. Direct comparisons are thus impossible, and one can hypothesise that these differences may be due to factors relating to age, to the relationship of the supporter to the demented dependant, to sex differences in 'help-seeking behaviour' or to sex differences in benefitting from contact with psychiatric services.

The finding that the partners of demented old people in the community do not, by and large, exhibit overt psychological disturbance should not be taken as an indication that they are free from burden and strain. Indeed, the results of a further study in the same general practice indicate that these families are under considerable strain, even although this is not manifested by overt psychiatric disturbance (Eagles *et al*, 1987).

The principal aim of research into the supporters of the demented elderly is to optimise, and possibly to prolong, these patients' care in the community. In maintaining an elderly demented patient at home one generally seeks to prevent the family from reaching the irreversible stage of 'total rejection' described by MacMillan (1960). How and whether this stage can be avoided is not yet known, and early intervention and support has been sensibly advocated as a means whereby it might be (Kay *et al*, 1970; Godber, 1977; Bergmann *et al*, 1978). Whether or not such support is effective, and whether it should be provided to all supporters, to supporters experiencing significant burden and strain, or only to supporters with overt psychiatric disturbance are all questions requiring further research.

The Mental Health of Elderly Couples

II. Concordance for Psychiatric Morbidity in Spouses

J. M. EAGLES, L. G. WALKER, G. W. BLACKWOOD, J. A. G. BEATTIE and D. B. RESTALL

A community sample of elderly married couples completed the 60-Item General Health Questionnaire and the Leeds General Scales for the Self-Assessment of Depression and Anxiety. Significant concordance was demonstrated between the spouses' scores on these scales. Concordance was higher for depression than for anxiety. There was little to support previous findings that wives are more likely than husbands to be concordant with an ill spouse. The spouse concordance rates for psychiatric morbidity were similar to those found in studies of younger married couples.

Although almost 50% of the population over the age of 65 live as one of a married couple (Registrar General Scotland, 1982a) little has been written about the relationship between marriage and psychiatric illness in the elderly. At an epidemiological level, it is well documented that the married elderly have a lower risk both of referral to psychiatric services and of being institutionalised with psychiatric illness (Sainsbury *et al*, 1965; Townsend & Wedderburn, 1965; Turner & Sternberg, 1978). However this may well reflect the benefits of social support in general, rather than a specific protective effect of marriage *per se*. While community surveys have found higher rates of functional psychiatric disorders in the elderly who are socially isolated (Kay *et al*, 1964*b*; Bergmann, 1971; Gruer, 1975), the reason for this relationship has not been established. Indeed, it is most probable that lifelong personality traits predispose towards both isolation and the development of neurotic illness in old age (Kay *et al*, 1964*b*; Bergmann, 1971). The epidemiological evidence is thus equivocal regarding the possible influence of marriage *per se* on the mental health of the elderly.

The relative lack of attention given to marital factors in geriatric psychiatry may be justified in that such factors may be very similar to those encountered, and researched, in younger patients. Two sources of evidence, however, suggest that the findings from younger couples are not generalisable and that older couples require to be studied in their own right.

Divorce statistics show that the longer one is married, the less likely one is to divorce (Crown, 1976). In 1981, 48% of all divorces in Scotland took place in those married for less than 10 years, while the corresponding figure for those married over 30 years was 5.5% (Registrar General Scotland, 1982*a*). One might infer from these figures that marriages become progressively stable as the duration of marriage lengthens.

On the other hand research conducted on younger married couples has produced considerable evidence that the concordance for neurotic disorder in spouses exceeds the rate that would be found by chance (Gregory, 1959; Kreitman, 1962; Nielsen, 1964; Merikangas, 1982), and this concordance rate has been shown to increase with increasing duration of marriage both for neurotic illness (Buck & Ladd, 1965; Ovenstone, 1973; Hagnell & Kreitman, 1974) and for neuroticism as measured on the Maudsley Personality Inventory (Kreitman, 1964; Hare & Shaw, 1965). While this relationship has not always been found (Pond *et al*, 1963; Agulnik, 1970), 'received wisdom' has it that 'the longer a marriage continues the more likely it is for both rather than one partner to be neurotic' (Freeman, 1983). If concordance does increase as a function of marital duration, it would follow that the marriages of the elderly would become increasingly polarised into partnerships of two stable or of two very unstable individuals. It is difficult to reconcile this picture with the low divorce rates in the elderly, when one considers the known association between marital disharmony and neurosis (Birtchnell & Kennard, 1983*a*,*b*) and between divorce and mental illness (Briscoe *et al*, 1973; Robertson, 1974; Merikangas, 1984).

Therefore, while the relationship between marriage and mental illness in the elderly has been the subject of little research, such evidence as there is points to conflicting conclusions. The main aim of the present study was to obtain further information on this relationship by using data from the screening investigation of elderly subjects described in the first part of this paper.

Method

Details of the screening investigation carried out on those aged 65 and over in a general practice population are given in the first part of this paper.

The subjects studied in this part of the paper comprised only the 274 married couples. Of the 548 spouses, 546 completed the 60-item General Health Questionnaire and 453 completed the Leeds General Scales for the Self-assessment of Depression and Anxiety.

Two methods were adopted to investigate the pattern of psychological disturbance in married couples. Firstly, within pairs correlation coefficients (Kendall's τ) between male and female scores on the GHQ and Leeds Scales were calculated, these data representing 'score concordance' between spouses. Secondly, 'case concordance' between spouses was examined. Data were analysed separately for males and females. A 'case' was defined as scoring above the cut-off point (described in part I of this paper) on any of the three scales i.e. 'GHQ cases', 'Leeds Depression cases' and 'Leeds Anxiety cases' were identified and analysed separately. 'Case concordance' was defined simply in terms of the spouse of a 'case' scoring above the cut-off point *on any one or more* of the three scales—the sample size did not justify analysing the six scale permutations separately.

Results

The total cohort's mean age and their scores on the GHQ and Leeds Scales are shown in the first part of this paper, and thus they will not be presented again.

The within pairs correlation coefficients between the spouses' scores on the GHQ and Leeds Scales are shown in Table I. The number of husband–wife pairs involved in each analysis is shown in brackets.

Four of the nine correlation coefficients are statistically significant. All correlations are positive, indicating a degree

Relative risk of wife concordance	1.75		2.22		1.47	

of concordance for minor psychiatric morbidity. The highest coefficient is between partners' scores on the Leeds General Depression Scale, ($r=0.16$; $P<0.005$).

Tables II and III show the rate of caseness of husband and of wives on each of the three scales. The frequency of spouse concordance is shown in the row below. The bottom rows of these tables show the 'relative risk of spouse concordance', which is derived from the ratio: rate of concordance in spouses of cases/rate of concordance in the spouses of non-cases.

Concordance in the spouses of cases on the three scales is consistently higher than in the spouses of non-cases. However, only for the wives of male Leeds Depression cases and of Leeds Depression non-cases does this difference reach statistical significance ($\chi^2=4.09$, d.f. 1, $P<0.05$).

The 'relative risk of spouse concordance' is consistently higher for women than for men, suggesting that women who have an ill husband may be more at risk of being ill than are men who have an ill wife. However, direct comparisons between husbands' and wives' concordance rates with spouse 'cases' were made using χ^2. For example, 21 wives and 30 husbands had spouses who were 'GHQ cases': spouse concordance was shown by six of the 21 wives and by four of the 30 husbands. These rates of spouse concordance are not statistically significantly different, nor are those of husbands and wives whose spouses are 'cases' on either of the Leeds Scales. There is therefore no statistical evidence to suggest that wives are more likely than husbands to be ill when they have an affected spouse, although the numbers in the analyses are relatively small despite the size of the initial screen.

Discussion

The results provide some support for concordance for minor psychiatric morbidity in elderly spouses. Statistically significant findings were obtained for 'score concordance' on four of the nine combinations of the three scales used. On the other hand, the results failed to provide statistically significant evidence for 'case concordance', although this may be due to the relatively small number of cases identified despite the size of the initial screen. As Tables II and III show, the 'relative risk of spouse concordance' does exceed that to be expected by chance (i.e. exceeds 1) on all three scales for both sexes.

The results of this study are to a large extent dependent upon the validity of the GHQ and Leeds Scales as screening tests for psychiatric morbidity in elderly subjects. Some of the difficulties relating to the use of these instruments, notably the GHQ, are mentioned in Part I of this paper and will not be repeated here.

Other studies of psychiatric morbidity in elderly spouses do not appear to have been undertaken. This may be partly because, as Dominian (1972) has pointed out, increased life expectancy has only recently lead to a relative proliferation of elderly married couples. However the present findings are consistent with those of Fengler & Goodrich (1979) who showed that when elderly men became ill, their 'morale' was interdependent with that of their wives.

Studies of younger married couples have consistently found higher concordance for mental illness than would be expected by chance, and those studies have been the subject of a full review by Merikangas (1982). Both she and Nielsen (1964) have summarised the main hypotheses as to why this should occur, and

TABLE III
Spouse concordance with female cases

	GHQ—Wife		*Leeds Depression — Wife*		*Leeds Anxiety — Wife*	
	Cases	*Non-cases*	*Cases*	*Non-cases*	*Cases*	*Non-cases*
Number	30	244	20	207	32	195
Husband concordance	4/30 (13.3%)	24/244 (9.8%)	4/20 (20.0%)	23/207 (11.1%)	4/32 (12.5%)	23/195 (11.8%)
Relative risk of husband concordance	1.36		1.80		1.06	

four of these hypotheses can be usefully considered in the context of the present study (1) that illness in one partner represents a reaction to illness in the other; (2) that partners may 'infect' each other with abnormal reactions; (3) that individuals with similar constitutions tend to marry one another ('assortative mating'); (4) that after referral for the illness of the first partner, identification of illness in the spouse is facilitated.

With regard to the present study, hypothesis (4) can be discounted since morbidity was not determined by referral to psychiatric services. Hypotheses (1) and (2) both refer to the relationship between husband and wife as constituting the important causative factor, and they may thus be collectively labelled the 'interaction hypothesis'. It is this hypothesis and that of 'assortative mating' which have been most forcefully advocated as determining the raised spouse concordance rates. Merikangas (1982) believes that assortative mating for personality traits (such as 'neuroticism') is sufficient to explain spouse concordance for all types of psychiatric disorder. Kreitman (1968*a*,*b*), on the other hand, concluded that while the findings in the functional psychoses were compatible with an assortative mating hypothesis, the interaction hypothesis provided a better explanation for the patterns observed in the neuroses, notably the pattern of increasing illness concordance with increasing duration of marriage. It is thus instructive to compare the present study's concordance rates with those from studies of younger patients.

The correlations of 'score concordance', as shown in Table I, are not high, the highest correlation (between spouses on the Leeds General Depression Scale) having a Kendall's τ of 0.16, ($P < 0.005$). The data on 'case concordance' (shown in Tables II and III) can be more readily compared with the findings in younger married couples, since it is this approach which has usually been adopted in such studies. The mean of the figures of the 'relative risk of spouse concordance' is 1.6, indicating that, if one has an ill spouse, then one has 1.6 times the risk of being ill than if one's spouse were well. Although there are difficulties in making comparisons with other studies ('cases' are usually defined through contacts with psychiatric services, for example), the figure of 1.6 is strikingly similar to the figures of 'morbidity risk' found in the spouses of younger psychiatric patients, where 'morbidity risk' indicates the ratio of the number of observed to the number of expected cases. The studies of Kreitman (1962) and Negri *et al* (1981) both derived a figure of 1.5 times that expected, while Nielsen's (1964) figure was 1.4. Gregory (1959), studying only psychiatric inpatients, found nine times more concordant spouses than expected by chance. Thus, the figure of 1.6 derived from the present study does *not* support the hypothesis that concordance for psychiatric morbidity steadily escalates into old age with increasing duration of marriage.

There are four main reasons why concordance for psychiatric morbidity in elderly spouses may not differ from that found in younger married couples. Firstly, the relationship between concordance and duration of marriage in younger patients may be an artifact of the methodology used in these studies (Merikangas, 1982). Secondly, marriages of neurotic individuals may be less likely to continue into old age. This could occur due to the increased mortality rates amongst those with neurotic illnesses (Sims, 1978), or because divorce is more common in those who are psychiatrically ill (Robertson, 1974; Merikangas, 1984) and in those who have higher levels of neuroticism on the Eysenck Personality Inventory (Thornes & Collard, 1979). Thirdly, the prevalence of neurotic illness in later life probably declines with increasing age (Kay, 1976; Nilsson & Persson, 1984). Fourthly, older people become more introverted as they age (Nilsson, 1983). This is associated with neurotic illness becoming more inwardly directed so that illnesses which 'forcefully impinge on others' are less common (Post, 1982).

This study does not bear out the findings of the studies of Kreitman (1964) and of Hagnell and Kreitman (1974), who found that wives are more likely than husbands to be concordant with an ill spouse. Partial support does derive from the finding that the 'relative risk of spouse concordance' was consistently higher in wives than in husbands with an ill spouse. However, women are about twice as likely as men to suffer from minor affective disorder (Weissman & Klerman, 1979), a fact confirmed by the present study. It might thus be expected that, given the stress of an ill spouse, a wife would be twice as likely as a husband to become psychiatrically ill. In this light, it might be considered surprising that wives were *not* shown to have significantly higher concordance with an ill spouse.

'Score concordance' between spouses was demonstrated for the Leeds General Depression Scale but not for the Leeds General Anxiety Scale. Adopting an 'interaction hypothesis' model this might be explained on the basis that it is less stressful to have an anxious rather than a depressed spouse, or that one is more likely to respond with depression to illness in one's spouse, than with anxiety. On the other hand, it is possible that assortative mating is more likely between spouses predisposed to developing depression than between those predisposed to becoming pathologically anxious.

Divorce occurs predominantly in the early years of marriage (Crown, 1976), and most of the current marriages between elderly couples did not have the 'advantage' of more liberal divorce laws at a time in the marriage when this 'advantage' was likely to have been utilised. Many marriages of elderly people thus presumably 'weathered the storm' without recourse to the divorce which might nowadays be sought. Studies of such marriages might provide useful background information for those working in the fields of marital therapy and counselling.

With increasing longevity, marriages lasting into old age will almost certainly become increasingly common. The continuing accent on community care for the elderly will thus require enhanced understanding of marital issues for the practice of geriatric psychiatry. Thus, to foster understanding of the marriages of younger people and to optimise the care of elderly patients, further research into the marriages of elderly couples should be given a high priority.

Acknowledgements

The authors are grateful to Professor D. F. Kerridge and his colleagues in the Aberdeen University Department of Statistics for their advice and practical assistance.

We wish to thank Miss Sybil McLeod and Mrs Sharon Wardell for their collation and processing of the data, and also for their typing of the manuscripts.

Dr C. J. Gilleard made valuable comments on an earlier draft of the first part of this paper.

The study was funded by a grant from the Scottish Home and Health Department.

Suicide in England and Wales, 1975–1984

G. M. G. McCLURE

An investigation of the suicide rate in the decade 1975–1984 in England and Wales revealed an increase in rate for males of all ages, and a small decrease for young females. The increase for males has been greatest in the 25–54 years group. There has been a decrease in the number of suicides by poisoning with solids and liquids (including overdoses) for both sexes. Rates for poisoning by vehicle exhaust gas and by hanging, strangulation and suffocation have increased substantially during this period. In males, suicides by these methods now exceed those due to poisoning by solids and liquids.

Suicide rates in England and Wales showed a steady decline in both sexes between 1963 and the early 1970s, due principally to a decrease in suicide in the older age-groups (Adelstein & Mardon, 1975). Rates for males decreased from 145 per million in 1963 to 95 per million in 1974, and rates for females from 99 to 64 per million during the same period.

The most important change in method of suicide during this period was a decrease in poisoning by domestic gas, which was being detoxified at this time. The total number of suicides from poisoning by domestic gas decreased from 2469 in 1962 to 50 in 1974. Suicide by poisoning with solid or liquid substances increased until 1964 and then remained relatively constant. In 1974 it was the most common method of suicide, with 1877 deaths by this means (794 males, 1083 females).

An investigation of suicide statistics between 1975 and 1980 reported that the downward trend in suicide rates had been reversed (McClure, 1984). 'Undetermined' deaths and 'accidental' deaths by causes comparable to suicide were also examined, because an apparent change in the suicide rate could be due to a change in the classification of deaths in these other categories where there was uncertainty whether death was accidentally or purposely inflicted (Sainsbury & Jenkins, 1982). This paper examines statistics for the decade 1975–1984.

Method

Suicide rates (ICD E950–E958) for England and Wales for the period 1975–1984 were obtained from annual publications (Office of Population Censuses and Surveys 1975–1984). In addition, 'undetermined' and 'accidental' deaths in categories comparable to suicide were also investigated (see appendix for comparable categories of cause of death). Changes by different methods and in different age-groups were examined during this period.

Results

Changes in suicide rate for England and Wales: 1975–1984 (all ages)

Changes in the suicide rate in England and Wales during the decade 1975–1984 are shown in Table I and Fig. 1. The suicide rate increased for males in each consecutive year between 1975–1984 from 91 per million to 118 per million, an increase of 30%. The total number of male suicides increased from 2184 to 2859 during this period. For females there was a small increase between 1975 and 1980, followed by a decrease between 1980 and 1984. The suicide rate for females decreased from 60 per million in 1975 to 57 per million in 1984, a decrease of 5%. The total number of female suicides decreased from 1509 to 1456 during the period 1975–1984.

The total of male and female suicides increased from 3693 (75 per million) to 4315 (87 per million) during the period 1975–1984.

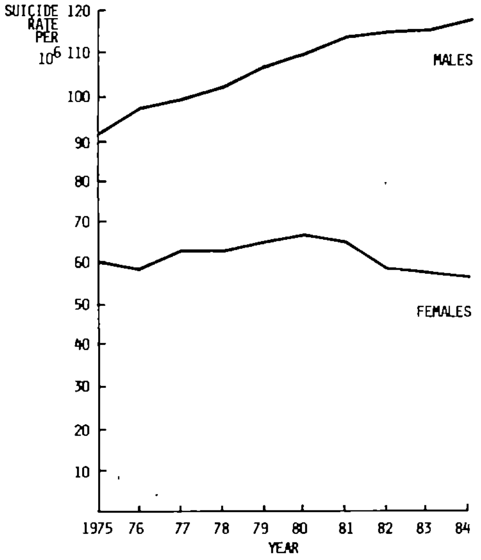

Fig. 1. Suicide rate for England and Wales: 1975–1984 (all ages).

Change in suicide rate by different methods 1975–1984

The changes in suicide rate by different methods for males and females are shown in Table II and Figs 2 and 3. For males, the number of suicides by hanging, strangulation and suffocation (E953) increased from 593 in 1975 (24.7 per million) to 891 in 1984 (36.8 per million). In addition, for males, the number of suicides by poisoning with gases other than domestic gas (E952) increased from 249 in 1975 (10.4 per million) to 773 in 1984 (31.9 per million). The majority of deaths in this category were by motor vehicle exhaust gas (E952.0), comprising 755 of the total 773 deaths for males. There was also a smaller increase in suicide by males using firearms (E955) from a total of 143 in 1975 (6.0 per million) to 205 in 1984 (8.5 per million). For males there was a decrease in the number of suicides by poisoning with solid and liquid substances, including overdoses (E950). The number of males committing suicide by this means decreased from 709 in 1975 (29.6 per million) to 495 in 1984 (20.4 per million).

For females the number of suicides by poisoning with solids and liquids, including overdoses (E950) also decreased during the period under review. The number of female suicides by this method decreased from 969 in 1975 (38.4 per million) to 678 in 1984 (26.6 per million). There was an increase in female suicides by hanging, strangulation and suffocation (E953) from a total of 220 in 1975 (8.7 per million) to 326 in 1984 (12.8 per million). In addition, there was an increase in suicide by gases other than domestic gas (E952) for females, with the number increasing from 27 in 1974 (1.1 per million) to 90 in 1984 (3.5 per million); 84 out of the total of 90 suicides by this method were by motor vehicle exhaust gas (E952.0).

TABLE II

Numbers (and rates per million population) for suicide and self-inflicted injury, classified by different causes, in 1975 and 1984 (all ages)

Cause of death (ICD and classification)		*1975*		*1984*			
		Number	*Rate*	*Number*	*Rate*	*Change in rate 1975–1984*	
E950 Poisoning by solid or liquid substances	Male	709	29.6	495	20.4	− 9.2	−31%
	Female	969	38.4	678	26.6	−11.8	−31%
E951 Poisoning by gases in domestic use	Male	19	0.8	10	0.4	− 0.4	[1]
	Female	4	0.2	1	0.04	− 0.16	[1]
E952 Poisoning by other gases and vapours	Male	249	10.4	773	31.9	+21.5	+207%
	Female	27	1.1	90	3.5	+ 2.4	+218%
E953 Hanging, strangulation and suffocation	Male	593	24.7	891	36.8	+12.1	+49%
	Female	220	8.7	326	12.8	+ 4.1	+47%

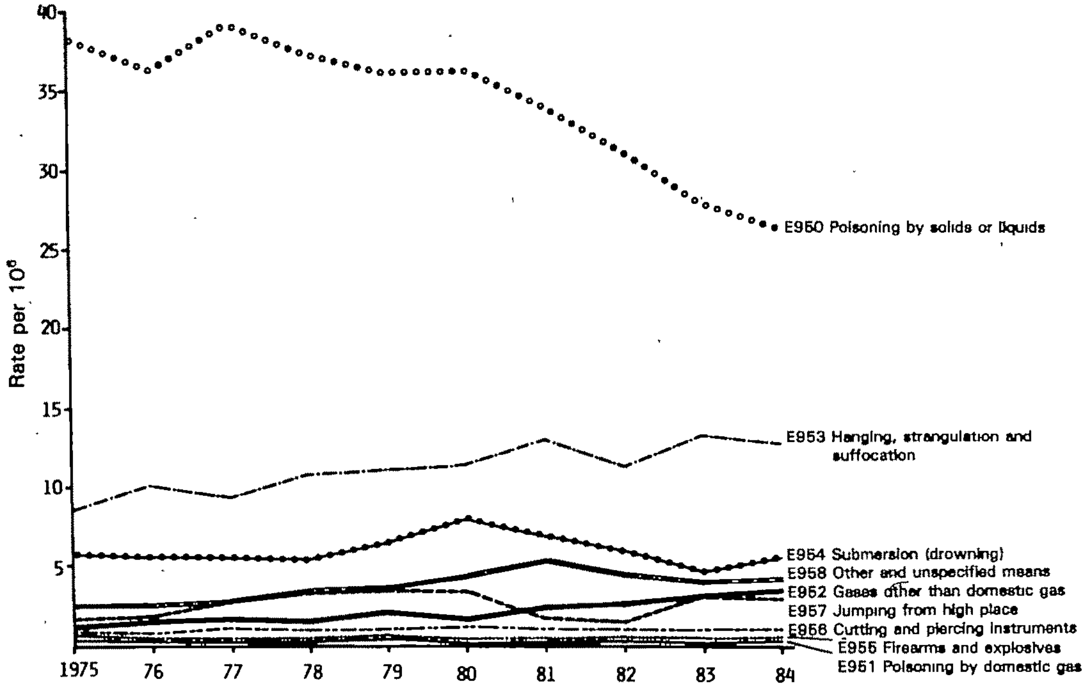

FIG. 3 Suicide rate by different causes (females) for England and Wales: 1975–1984.

TABLE III

Rate (per million population) of suicide and self-inflicted injury in different age-groups in 1975 and 1984

	1975		1984		Change in rate 1975–1984	
Age group	*Males*	*Females*	*Males*	*Females*	*Males*	*Females*
5–14 years	<1	<1	<1	<1	—	—
15–24 years	64	28	75	16	+11(+17%)	−12(−43%)
25–34 years	105	49	140	38	+35(+33%)	−11(−22%)
35–44 years	113	68	165	64	+52(+46%)	−4(−6%)
45–54 years	138	99	182	98	+44(+32%)	−1(−1%)
55–64 years	154	106	168	107	+14(+9%)	+1(+1%)
65+ years	170	106	190	103	+20(+11%)	−3(−3%)

Change in suicide rate in different age-groups: 1975–1984

Table III shows the analysis by age of suicides in 1984, and the change in rate for each group between 1975 and 1984. The suicide rate has increased between 1975 and 1984 for males in all age-groups, particularly in the 25–54 years group. For females, the rate has decreased in the age-group 15–34 years, with little change occurring in females over 35 years.

'Undetermined' and 'accidental' deaths

Categories of 'undetermined' and 'accidental' deaths by causes comparable to suicide are shown in the appendix. Between 1975 and 1984 the 'undetermined' death rate increased by 7 per million to 38 per million for males, and remained unchanged for females at 25 per million. The summation of 'undetermined' death rate plus 'accidental' death rate for causes comparable to suicide showed a small decrease for males of 4 per million to 75 per million in 1984. This is insufficient to account for an increase in suicide rate of 27 per million between 1975–1984. For females, the summation of 'undetermined' death rate plus 'accidental' death rate for causes comparable to suicide decreased by 8 per million to 41 per million in 1984. This change is in the same direction as the small decrease in suicide rate for females between 1975–1984. It is concluded that the change in suicide rate between 1975–1984 is unlikely to be due to a simple change of classification concerning 'undetermined' or 'accidental' deaths.

'Undetermined' and 'accidental' deaths by specific causes

'Undetermined' and 'accidental' deaths by specific causes, comparable to suicide are shown in Table IV. By comparing the changes with those for suicide in Table II, it can be seen that along with the decrease in suicide by poisoning with solid or liquid substances there was also a decrease in 'undetermined' and 'accidental' poisoning by this method. It is therefore unlikely that the decrease in suicide by this method can be explained by a change of classification to 'undetermined' or 'accidental categories'. Similarly, although there was a small decrease in 'undetermined' and 'accidental' poisoning by gases, this is insufficient to account for the increase in suicide by gases other than domestic gas (E952). (In fact, closer examination of the statistics underlines the fact that the increase in suicide by motor vehicle exhaust gas was *not* caused by a change of classification; 'accidental' deaths by this means (E868.2) *increased* for males from 16 in 1975 to 31 in 1984 and decreased for females from 2 in 1975 to 1 in 1984). In addition, the other major change in suicide, by hanging, strangulation or suffocation (E953), cannot be explained by a change of classification to 'undetermined' or 'accidental' death. There was an increase in this category for males, and the small decrease of 0.6 per million for females for 'undetermined' or 'accidental' hanging, strangulation or suffocation is insufficient to account for the increase of 5.1 per million in suicides by this method.

It is also of interest that the smaller changes in suicide by causes E954-E958 (with the minor exception of E955 for females) are not explicable in terms of a change in classification to 'undetermined' or 'accidental' death.

'Undetermined' and 'accidental' deaths by different age-groups

'Undetermined' and 'accidental' deaths for categories comparable to suicide in different age-groups are shown in Table V. The decrease in 'undetermined' and 'accidental' deaths in males under 24 years casts doubt on the reported increase in suicide in this group. For males aged 25–44 years, however, the reported increase in suicide cannot be explained by a change of classification to 'undetermined' or 'accidental' deaths which also increased between 1975–1984. For males aged 45+ years, decreases in 'undetermined' and 'accidental' deaths may account for part, though not all, of the recorded increase in suicide rate.

For females, there was a decrease in 'undetermined' and 'accidental' deaths for categories comparable to suicide in all age-groups except 25–34 years, where there was a small increase. The decrease in suicide recorded in females aged 15–34 years cannot be explained by a change of classification to 'undetermined' or 'accidental' death.

TABLE IV

Numbers (and rates per million population) of 'undetermined' plus 'accidental' deaths, classified by different causes 1975 and 1984 (all ages)

Cause of death (ICD and classification)		*1975*		*1984*		*Change in rate 1975-1984*	
		Number	*Rate*	*Number*	*Rate*		
E980+E850-66 Poisoning by solid or liquid substances	Male	570	23.8	491	20.2	−3.6	−15%
	Female	736	29.1	484	19.0	−10.1	−35%
E981/2+E867/8/9 Poisoning by gases (all gases)	Male	121	5.0	132	5.4	+0.4	+8%
	Female	63	2.5	36	1.4	−1.1	−44%

1. For categories comparable to suicide

Discussion

The suicide rate for males increased for each consecutive year during the period 1975-1984, with an overall increase of 30%. During the same period there was little change in the suicide rate for females. Although there was an increase in rate for males of all ages, this was most apparent in the 25-54 years group. There was a decrease in the suicide rate for females in the 15-34 years category.

Suicide by self-poisoning with solids and liquids decreased in both sexes, and there was an increase in poisoning by motor vehicle exhaust gas and by hanging, strangulation and suffocation, particularly in males. Examination of the changes in 'undetermined' and 'accidental' deaths in categories comparable to suicide indicate that the changes observed in the suicide rate could not be explained simply by a change of classification. They are likely to represent real changes in suicide.

The changes observed may not be due to any single cause, but may be multifactoral in origin. It is of interest that the decrease in suicide by poisoning with solids and liquids parallels a decrease in admissions to hospital for adverse effects of chemical substances, which peaked in 1976 and has since been in decline.

(Central Statistical Office, 1982). The greatest decrease in suicide by this method occurred in young females, age 15–34 years—a group which has been most prominent for overdosing. The indications are, therefore, that the popularity of this phenomenon has *decreased* in the last decade, following the 'epidemic' of the 1960s and early 1970s.

The decrease in suicides by poisoning with solids and liquids has been offset by an increase in poisoning with vehicle exhaust gas and by hanging, strangulation and suffocation. An explanation must be sought for the substantial increase in suicide rate, particularly by these methods, in males in the 25–54 years group. Possible factors include unemployment, job insecurity, alcoholism and disrupted family life (as indicated by divorce rates). Unemployment, wine and spirit consumption and the number of divorcees in the population have all shown an increase during the period under review (Central Statistical Office, 1985) and these factors may particularly have affected young male adults.

Hanging has traditionally been employed by males, and may have increased because of decreased availability of domestic gas, and decreased confidence in the lethality of overdosing. Self-poisoning with vehicle exhaust gas has increased, particularly in males, probably because they are more commonly owners and drivers of motor vehicles than females. Both these methods are now more common for males than suicide by self-poisoning with solids or liquids. Hanging, strangulation and suffocation have been at high levels in the past, but the phenomenon of vehicle exhaust gas poisoning is new. The increase in both these methods gives cause for concern, as in neither case can the agents be made less readily available. Hopes for a decrease in the rate must therefore rely on dealing with the causes of suicide and this in turn depends upon a greater understanding of causative factors.

The Dexamethasone Suppression Test and Prediction of Outcome in Patients Receiving ECT

C. L. E. KATONA, C. R. ALDRIDGE, SIR MARTIN ROTH and J. HYDE

Twenty-six in-patients satisfying DSM-III criteria for major depressive episode were assessed using the Newcastle Diagnostic and ECT Predictor Scales and the dexamethasone suppression test (DST), prior to commencing a course of electroconvulsive therapy (ECT). The Newcastle ECT Predictor Scale was successful in predicting both immediate outcome and outcome over the 6 months following ECT; the DST was unsuccessful in predicting either immediate or 6-month outcome.

Abnormalities in the dexamethasone suppression test (DST) have been claimed to have a high degree of specificity for melancholia or endogenous depression (Carroll *et al*, 1981). The DST has also been proposed as a possible guide to the prediction and monitoring of response to electroconvulsive therapy (ECT), with an initial non-suppressor DST predicting a good response to ECT (Albala *et al*, 1981; Coryell, 1982).

The present study compared the ability of the DST to predict ECT response with that of the following clinical scales:

(a) The Newcastle ECT Predictor Scale (Carney *et al*, 1965), which was constructed specifically to identify those patients most likely to respond to ECT.

(b) The Newcastle Scales for the Diagnosis of Depressive Syndromes (Carney *et al*, 1965; Gurney, 1971), which were devised to distinguish between non-endogenous and endogenous forms of depressive illness—the latter generally being considered as the disorder most likely to respond to ECT (Kendell, 1981).

Method

Selection of patients

Twenty-six inpatients satisfying DSM-III criteria for major depressive episode, who had been prescribed ECT by the clinicians responsible for their care, were included, provided that: (i) they did not fulfil the exclusion criteria for the DST suggested by Carroll *et al* (1981); (ii) they showed no evidence of dementia; (iii) they were willing to give informed consent to take part in the trial; and (iv) that it was possible to carry out the pretreatment assessment before the first ECT was administered.

Assessment conditions

The responsible clinicians were kept blind to the researcher's initial assessments, to the Hamilton Ratings and to DST results. Their clinical notes were examined by the researcher assessing immediate clinical outcome and 6-month outcome.

Initial assessment

Patients were interviewed initially by an observer who had access to the case notes; a DSM-III diagnosis was made, and the Newcastle Diagnostic and ECT Predictor Scales completed. Age, sex and concurrent medication were recorded. A separate observer, blind to these assessments, completed the 17-item Hamilton Depression Rating Scale (HDRS) (Hamilton, 1960).

Dexamethasone suppression test

The test procedure was similar to that described by Carroll (1982), with 1 mg of dexamethasone administered orally to each subject at 11 p.m., and blood samples taken at 4 p.m. and 11 p.m. the following day. Plasma cortisol assays were performed with the 'Amerlex' radioimmunoassay kit, using a technique described in detail by Katona & Aldridge (1985).

All the above ratings and tests were carried out between 1 and 7 days before the first ECT; normally, the initial interview was carried out and the dexamethasone administered 2 days before ECT, with the cortisol levels taken and the HDRS completed one day before the first ECT. ECT was administered two to three times weekly (according to clinical judgement), using an Ectron IV machine delivering a high-energy current. The length of the course of treatment was decided by the responsible clinicians.

Assessment during ECT

Wherever possible, the DST and HDRS were repeated the day after the fourth ECT. After the course of ECT, a further DST was carried out and the HDRS completed by the original observer (blind to the original assessments and to DST results) as soon as possible after the clinical decision had been made to give no more ECT. Normally, this was between 1 and 2 weeks after the final ECT. The DST was repeated on the day of the final HDRS. Medication at the end of the course of ECT was recorded, as was the number of ECTs and whether treatment was unilateral or bilateral.

Assessment of immediate outcome

In addition to the final HDRS, a global assessment of outcome was made by another observer, who was blind to the initial assessments, DST results and HDRS Scores. This assessment was based on a scrutiny of the clinicians' notes and nursing notes for the period up to 2 weeks after the final ECT, or until discharge, whichever was the sooner. The ratings were made on a three-point scale: Good = No evidence of depression at the end of treatment; Intermediate = Evidence of improvement but still significantly depressed at the end of treatment; Bad = No improvement, significantly depressed at the end of treatment.

Six-month follow-up

To obtain a limited form of 6-month follow-up assessment, the investigator who had assessed immediate outcome examined the subjects' in-patient and out-patient notes, 6 months after the course of ECT, for unequivocal evidence of deterioration in their mental state, e.g. readmission for further ECT or attempted or completed suicide. General practitioners were contacted about those patients who had been discharged from the out-patient clinic. If there was no evidence of relapse following a good immediate outcome, the 6-month outcome was also classed as good. Patients who were still depressed on discharge or who relapsed after a good immediate outcome were classed as having a poor outcome over 6 months.

Results

Twenty-six patients were studied, ranging in age from 20 to 82 years (mean 54.1). Sixteen patients were women; 24 fulfilled DSM-III criteria for melancholia, and four for bipolar disorder. Their initial assessment data are in Table I.

TABLE I
Initial assessment data (n = 26)

Newcastle 1965 Diagnosis	18 endogenous	8 not endogenous
Newcastle 1971 Diagnosis	20 endogenous	6 not endogenous
ECT Predictor	17 good outcome	9 poor outcome
Initial DST	15 non-suppressor	11 suppressor
Initial HDRS	Range 18–38 (median 25)	

Almost all patients received concurrent psychotropic medication during the course of ECT: 19 received antidepressants, 18 neuroleptics, 12 benzodiazepines and three lithium. Twenty-three patients received bilateral ECT and three unilateral; the number of treatments given ranged between three and 11. Subsequent analysis revealed no significant relationship between either number of ECTs or concurrent medication and outcome or DST results. It will be seen that 15 patients (58% of the total sample and 60% of the DSM-III melancholics) were non-suppressors, according to Carroll's (1982) criteria of 4 p.m. and/or 11 p.m. post-dexamethasone cortisol ≥138 nmol/litre.

Immediate outcome

On case-notes assessment, three patients had a bad immediate outcome, eight an intermediate and 15 a good immediate outcome. The final HDRS rating scores are illustrated in Fig. 1: the final scores fall into three bands, according to the three categories of outcome based on case-note assessment. There were only two discrepant results, both in patients with intermediate outcome on this assessment. The independent HDRS scores thus provide validation of the assessment of immediate outcome based on case notes. We have based further analysis on case-notes outcome assessment, rather than using an arbitrary HDRS cut-off point as the outcome measure. Intermediate and bad immediate outcomes are classed together as 'poor', since both left the patient 'still significantly depressed'.

Prediction of immediate outcome

Of the possible clinical predictors of outcome, the ECT Predictor Scale was strikingly successful (see Table II) being correct in all but four cases. Initial DST non-suppression was not associated with good immediate outcome; indeed, there was a striking though not significant trend for suppressors to have a better immediate outcome than the non-suppressors.

Using final HDRS score ≤6 as the criterion of recovery following Coryell's (1982) criteria, 12 patients had recovered and 14 had not. Repeating the calculations led to the same conclusion — that only the ECT Predictor Scale succeeded in predicting immediate outcome, though with a slightly lower degree of significance.

Prediction of outcome over 6 months

Of the various potential predictors of outcome, only the Newcastle ECT Predictor Scale succeeded in predicting outcome over 6 months.

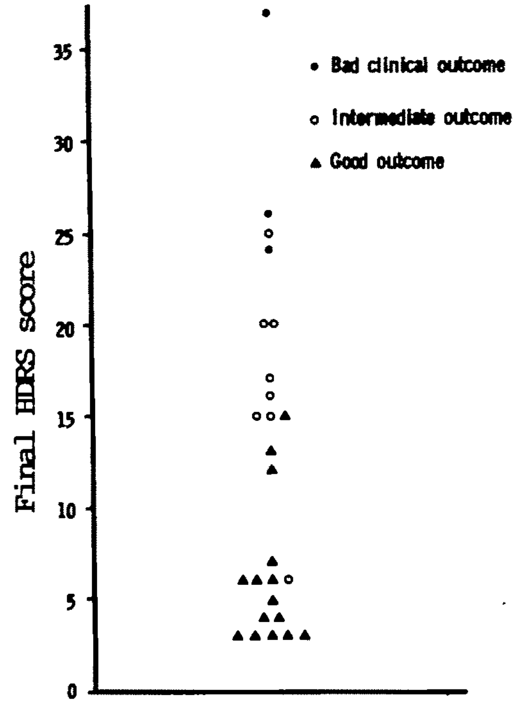

FIG. 1 Final HDRS scores and independent assessment of immediate outcome.

TABLE II
Relationship between predicted and actual outcome

	Immediate outcome			*6-month follow-up*		
	Good	*Poor*	*P*[1]	*Good*	*Poor*	*P*[1]

Good (17)	14	3	<0.001	7	10	<0.03
Poor (9)	1	8		0	9	

[1] Fisher's Exact Test

Serial DSTs and outcome

Serial DST results and immediate and 6-month outcome are shown in Table III. There was a non-significant trend for persistent non-suppression to be associated with poor immediate outcome, and it should be noted that the nine patients whose initially abnormal DSTs remained abnormal after treatment included three whose DSTs converted to suppression during treatment, only to revert back to non-suppression at the end of treatment.

There was no significant correlation, either before or after treatment, between mean post-dexamethasone cortisol levels and concurrent HDRS scores. However, there was a highly significant correlation (Spearman's rho = 0.55, $P = <0.01$) between changes in HDRS scores and changes in mean post-dexamethasone cortisol levels.

TABLE III
Serial DSTs and outcome

	Immediate outcome		*6-month follow-up*	
	Good	*Poor*	*Good*	*Poor*
Initial DST Suppression (11)				
Persistent suppression (10)	7	3	3	7
Not retested (1)	1	0	1	0
Initial DST Non-suppression (15)				
Suppression after treatment (4)	3	1	1	3
Non-suppression after treatment (9)	3	6	1	8
Not retested (2)	1	1	1	1

Discussion

All the patients in the study had been prescribed ECT on clinical grounds; most had a DSM-III diagnosis of melancholia and most were endogenous depressives on either or both of the Newcastle Diagnostic Scales. In this sample, the pretreatment DST did not predict immediate outcome, and thus our results do not support those of Coryell (1982). In Coryell's study, the DST only predicted outcome according to one of the two methods used to assess outcome, whereas in our series, the DST failed to predict immediate outcome according to either of Coryell's measures.

The Newcastle ECT Predictor Scale was successful at predicting both immediate and 6-month outcome, in contrast to the Northwick Park Study (Clinical Research Centre, 1984), which showed no significant correlation between score on the ECT Predictor Scale and improvement after real or simulated ECT. In our series, the ECT Predictor Scale seemed to be particularly effective in identifying those patients with a poor immediate outcome, and could perhaps be used to help 'screen out' such patients before treatment. In certain clinical situations, such as high suicide risk, even a small chance of improvement might be worthwhile, and the ECT Predictor Scale may best be seen as an adjunct rather than an alternative to clinical judgement.

Diagnosis according to the 1965 and 1971 Newcastle Scales failed to predict outcome. This is perhaps not surprising, in view of the fact that the diagnostic scales were devised in an effort to sharpen the phenomenological distinction between 'neurotic' and 'endogenous' forms of depression, rather than to predict response to a specific form of treatment. The nature, purpose and mathematical structure of scales developed to assist clinical diagnosis and those intended to aid prediction in a specific context are quite different (Roth, 1978).

Like Coppen *et al* (1983), we found a significant relationship between change in mean post-dexamethasone cortisol levels and change in HDRS scores after treatment. Serial post-dexamethasone cortisol levels may perhaps be useful in monitoring recovery from depressive illness. It is suggested that the magnitude of the change in cortisol level may be of greater significance than a knowledge of whether or not the cortisol level has crossed the boundary from non-suppression to suppression, since the latter may represent a relatively small change in post-dexamethasone cortisol level.

Fluctuations in DST status during treatment were observed in three cases; all three patients had a poor immediate outcome, in spite of early normalisation of an initially abnormal DST. This instability in DST status (which has also recently been reported by Bowie (1984)) may limit the extent to which early conversion from non-suppressor to suppressor responses can be taken to predict a good subsequent clinical outcome, as has been claimed by Albala *et al* (1981). Yerevanian *et al* (1983) have suggested that persistent non-suppression after ECT or anti-depressants is a predictor of early relapse after an apparently good immediate outcome. Using our more stringent criterion of recovery, a final non-suppressor DST was associated more frequently with an incomplete recovery than with relapse after a convincingly good immediate outcome.

Conclusions

The findings of this study add to the doubts concerning the clinical value of DST and do not support the use of the DST as a means of predicting immediate response to ECT or relapse within 6 months of ECT. The Newcastle ECT Predictor Scale may be of value in predicting response to ECT, particularly if it is used to 'screen out' patients who are unlikely to make a good response. In those patients with an initially abnormal DST, subsequent DST status during a course of ECT is sometimes unstable, and early normalisation during ECT is not a reliable predictor of a good subsequent outcome. The correlation between mean post-dexamethasone cortisols and concurrent HDRS scores may render the former a useful index of recovery from a depressive illness. We therefore conclude that the DST remains of limited value in the management of patients being considered for ECT, whereas the Newcastle ECT Predictor Scale may be more effective than has hitherto been recognised.

Acknowledgements

Huntington's Chorea:

Some Psychodynamics seen in those at Risk and in the Responses of the Helping Professions

B. MARTINDALE

The autosomal dominant mode of inheritance of Huntington's Chorea (HC) has been established for over 100 years. Strong psychological defences against the acceptance of this knowledge are commonly found both in professionals and in Huntington families and relatives who are at risk. One consequence of maintaining these defences is the continuing transmission of the gene, and therefore the disease, to succeeding generations. The defences of professional persons protect them from the difficult and unsettling task of providing genetic counselling to healthy relatives at risk. An increase in awareness of the psychodynamics involved may lead to constructive thinking about the current deficiencies in care and counselling services provided for these families.

The clinical features of HC have received prominent attention in the literature since George Huntington's lucid description over a century ago (Huntington, 1872; Heathfield, 1973). The fact that the disease is inherited by an autosomal dominant gene has also been recognised since that time. Considerable attention has been directed to scientific investigation of the mechanism by which the abnormal gene causes the degeneration of the central nervous system (Chase *et al*, 1979). This research has not led to any breakthrough in treatment though the development of a genetic marker may well do so (Harper, 1983).

With this in mind it is of considerable interest that so little attention has been paid until recently to the possible benefits of providing skilled genetic counselling services to these families. If those at risk were to be fully informed they might well decide to limit their family size: evidence that this is so has been published (Harper, 1981; Carter *et al*, 1983). Both authors suggest that skilled counselling could very substantially reduce the prevalence of the gene in a few generations. There are about 5-6000 persons with the disease in Britain and a further 50 000 whose lives are burdened by being at risk or married to someone at high risk (Office of Health Economics, 1980).

It seems very important to try to understand why so many of these people receive no counselling even when they have been in contact with otherwise skilled professionals (Martindale & Yale, 1983). It is also important to understand why some families and individuals may not be able to use information that is readily available to them.

The following psychodynamic insights are based on 10 years experience with professionals involved with about 70 HC families as well as direct personal contact with HC patients and those at risk of HC.

Pathological defences seen in some people at risk of HC

I define defence mechanisms as pathological when they are so extensive or rigid that they prevent the individual gradually coming to terms with the possible implications of HC for them and their family's lives. I will emphasise and illustrate the serious problems that follow when these defences are so extensive.

I will also demonstrate the possible developmental background of some of these defences and how the persistence of this disease in many families is related to these defence mechanisms and their interaction with similar mechanisms in professionals.

Denial or disavowal

This term refers to a defence whereby the person refuses to recognise a traumatic perception.

A woman with multiple problems from advanced HC was severely handicapped by her chorea and in a hallucinatory psychotic state. She had recently set fire to her kitchen. Her denial was absolute. "Thank you for coming – we haven't any problems – you don't need to come again". This woman had four children still living with her, aged 8–18, and contact with this family revealed that the older the child, the greater the use of denial of the family problems, especially of the knowledge that mother's and grandfather's

HC had any possible implications for their lives. However, the youngest child was able to talk spontaneously about these worries to the professionals. Prolonged contact with the family led to the firm impression that the family atmosphere of denial, stemming from the parents' denial was a defence mechanism that became increasingly firmly adopted as a personality characteristic as each child grew older and was continually exposed to the family's inability to talk about very painful matters.

It would seem likely that the ability to recognise and come to accept the onset of the disease in oneself might be heavily determined by the pre-morbid defences of the individual.

Reaction formation

This is a defence resembling counter-phobia, whereby an unacceptable feeling or impulse is unconsciously mastered by exaggeration of its opposite.

In some Huntington's families the large number of children can be understood as a result of this defence mechanism. The parents have unbearable feelings of guilt in connection with the knowledge of the suffering that any child could experience from being at risk of the family illness. These feelings cannot be tolerated consciously and in order to defend against them and preserve the wish to have healthy children, the person behaves as if there is *nothing* to worry about – as if to say "Look, I can have an endless number of children without fear for myself or them".

Rationalisation

Rationalisation is the use of logical or acceptable explanations by a person for his attitudes, actions, etc., with the unconscious aim of disguising or not perceiving the true motives.

Whittier gives an excellent example of a mother who consciously knows that her daughter has a 50% risk of developing HC but finds successive rationalisations for keeping this information from her at every stage of her development (for example, "she's too young"; later "I don't want to spoil her chances of dating"; later still "I'm frightened that her engagement will be broken off" etc.). The mother's unconscious use of successive rationalisations was probably to protect herself from her guilt, sadness and bitterness and from her daughter's anger at her possible fate (Whittier *et al*, 1972). The rationalisation is pathological in that it hides the truth of the situation from her daughter and gives her no opportunity to face this reality and decide whether to adjust her life accordingly. In this case, the daughter goes ahead and has a child.

The risk of HC is transmitted to a further generation in ignorance of this risk as a result of mother's defences.

Projection and projective identification

These are very common defence mechanisms used in a variety of ways by those at risk of HC or suffering from the disease. The reason for HC families often avoiding health services are complex and multiple. Often there has been a long history of inadequate if not deleterious responses by professional services. However, in many cases, contact with health services would mean facing the distressing personal problems that Huntington's families would like to hide from. By the processes of projection or externalisation the health services are then felt to be the *source* of the problem and are in turn avoided.

A man trying to avoid his awareness that he was in the early choreiform stages of HC did not attend any health service agency but went to a faith-healer several hours drive away and was reassured that he was not suffering from HC. His mood picked up for a few months (the faith healer having colluded with and reinforced the denial). The HC progressed but he continued to avoid (by denial) allowing his perceptions of his illness becoming fully conscious. Medical services were actively avoided as they were experienced only as useless and/or persecutory. This can be understood as a concrete expression of the feared useless and/or persecuting ill part of himself that he was trying to rid himself of or attribute to an external source. He was, therefore, unable to seek care. His continuing desperate attempts to maintain his denial of the progressive illness and incapacity were successful only at the cost of a further breakdown of his ego in the form of a frank hallucinatory psychotic state. Possibly this served the maintenance of his denial by ensuring that information about his condition from his perceptions was further fragmented.

The defences adopted by some professionals coming into contact with HC families

The previous section briefly illustrated some psychological mechanisms that protect persons at risk from HC from experiencing painful feelings about the disease. It demonstrated that these protective mechanisms paradoxically increase the chances of suffering, especially in the next generation.

Similar defences exist in professionals who come into contact with HC families.

Again, these defences both protect the professional from disturbing feelings and play a very important part in perpetuating the disease, as discussion and counselling with the family about the disease are avoided. It is hoped that increased awareness of these defence mechanisms will alert professionals to their unconscious tendency to avoid providing facilitating counselling for these families. Evidence will be given that this evasion is currently very common and ranges from complete avoidance by the professional of any contact with the HC family to types of involvement that avoid the central issues.

Denial

Denial by professionals of the genetic implications of the disease is common (Martindale & Yale, 1983). It protects them from feeling sadness, hopelessness and horror at the physical and psychological problems of the families. Denial of the genetic implications means that the professional can avoid considering offering genetic counselling.

I have seen neurologists' letters to general practitioners where various details of the disease have carefully been spelled out but reference to the genetic implications for relatives seems to have been selectively omitted. The general practitioner may also then not consider counselling for relatives because of his own denial or from ignorance about the genetic facts.

In one family where the diagnosis was not discussed by professionals with the family, seven children were born in the next three years to relatives who were at risk.

Sometimes, exaggerated attention to a less important detail of the person may have the same function of avoiding the aspects of the disease that the physician finds most uncomfortable.

For example, a neurologist requested a GP's help to get an autopsy because of an unusual clinical feature in a man with probable HC. He did not mention that an autopsy diagnosis would also have been very helpful in counselling the young adult daughters who had never been mentioned by the neurologist in his letters to the general practitioner.

Another hospital specialist told me he had been seeing an HC patient over a number of years mainly for teaching purposes, the emphasis being on demonstrating the movement disorder that would captivate the student audience. The specialist had given no consideration to conveying information about the existence of this genetic disease to those medically responsible for the man's nine siblings and their increasing number of children, now 21 in number (let alone to teaching his students about the psychosocial aspects of the disease).

Displacement of responsibility

Frequently, the professional making the diagnosis will say that he assumed that one of the other disciplines involved had taken on the genetic counselling but it turns out that no arrangements had been made and indeed, other disciplines may have made the same assumption about the diagnostician. Responsibility may well be passed on within a discipline to the most junior member—using the pretext of an interesting case for the junior. I have met several HC families who remember the chain of professionals who were given responsibility for their care for a few weeks only—just enough time to begin to establish a relationship before the professional left.

Projection

A social worker was the legal guardian of three children in care. He said it would be too upsetting for the *children* to see their mother who was in hospital with HC. He had not arranged any visits. When encouraged to do so it transpired that *he* was very anxious about how *he* would cope on this visit, whereas the children were quite keen to visit and coped well with it.

Rationalisation

A doctor explained that he had decided not to counsel the 28-year-old daughter of an affected woman because she was single and therefore the disease had no current relevance to her life!

It is very common for doctors and parents to use conscious explanations to facilitate their denial that children commonly know about the hereditary implications of their parent's illness. If the doctor can allow himself to appreciate this, he will often find the child is full of fantasies and convictions that may be even worse than the reality. They often believe that they will definitely get the illness because of some physical resemblance or personality characteristics, rather than the fact that they have a 50% chance of not getting the disease.

If it is denied that children can be aware of the genetic implications, endless theoretical discussions can occur about why the children should not be told.

When I first worked with an HC family, senior colleagues advised me to spare the children any discussion about HC for a few years yet. It took me some while to realise that I had plenty of clues that informed me that all the five children, aged from 7 to 21, were already distressingly preoccupied with the genetic implications but totally unable to discuss it amongst themselves, believing that the others in the family did not know, or want to know. They were additionally burdened with a professional who also, at this point, did not seem to want to know.

Incurability

Huntington's families are threatening to those professionals who have difficulty working with conditions that cannot be cured. A frequent response is to say or feel that there is nothing that can be done for those families and not to offer them further professional help. It is, of course, true that nothing can be done to reverse the progress of the neurological condition but many disciplines have very useful contributions to make that can considerably ameliorate many of the related problems that can become distressing if unattended to. The stories of Tom told by Gardham (1982) and of Ian Miller by Phillips (1982) are worthwhile reading for anyone who is unaware of either the consequences of professional neglect or the benefits of skilled professional care and facilities.

Furthermore, it is my experience, and that of others, that the quality of care given to HC victims, as perceived by their children, significantly influences the children's likelihood of facing their own possibility of developing the disease and their ability to make use of professional services (Wexler, 1979).

Discussion

Huntingdon's chorea is a disease leading to a very wide range of physical and psychosocial problems. Many different disciplines have areas of expertise that can contribute to the provision of skilled comprehensive care (psychiatrists, neurologists, geneticists, social workers, general practitioners, nurses and occupational therapists as well as the self-help group COMBAT etc.).

However, a previous paper (Martindale & Yale, 1983) described the outcome of a field survey. This demonstrated that opportunities for preventive medicine, especially genetic counselling, were being avoided by professional workers of all disciplines in nearly every Huntington's family uncovered by the survey.

This article emphasises that, whichever discipline is involved, psychodynamic factors can play a very major part in determining whether any care is given and the quality of that care. There is nothing unique about HC in this respect except that the particularly horrific nature of the disease makes it even more likely that psychological defences against involvement will occur. I especially want to emphasise that these defences play a very major part in determining the perpetuation of the disease. They protect families and professionals from accepting the painful reality of the disease and thereby expose them to the consequences of going about matters as if there was nothing disturbing to worry about. For adults at risk, this often takes the form of having children without facing the reality of their own and their children's chances of developing HC. For the professional, it may take the form of not taking any measure to counsel fully those at risk and their relatives. Both family and professional are, therefore, playing a major part in perpetuating the disease, through their understandable difficulties in facing painful realities.

The goals of counselling should not be to make judgements about whether those at risk should or should not have children, but to foster emotional insight so that they can make informed decisions about their future lives. Those who do offer counselling often feel it should only be with *adults* at risk (Harper, 1981). However, if one takes a developmental view of personality organisation, one often finds that those adults at risk of HC have been exposed throughout their formative years to relationships with their families and with professionals in which the evidence of HC has been denied or information about HC has been distorted.

Some of the case material in this paper indicates how the family denial may become internalised and thus become an integral part of the developing personality of children in HC families. If one takes these points into consideration, it may be possible to differentiate, at the time of assessment, those at risk who may be able to make good use of a relatively brief series of information-giving counselling sessions from those who may need a long-term professional relationship, in which they can gradually develop the confidence to face painful matters they have habitually defended against. A further logical extension of my observations would be that families need help in facing the family illness when the children are young, especially when the illness is an integral part of family life. The full co-operation of the parents will need to be elicited to prevent any undoing of the counsellor's work with the children. Premature discussion of the genetic implications before an atmosphere of sufficient trust and support has been achieved may lead only either to denial becoming more entrenched, or to an increase in other forms of resistance to facing the illness. These may include avoidance of contact with the professional (Martindale & Bottomley, 1980).

It is also crucial that the various professionals potentially involved are in good enough communication with each other to clarify who is the best person to take on the counselling in each family. The defences of individual professionals that have been described often prevent this communication and clarification, when no one wants to take on the counselling. It does not seem to me that counselling should be necessarily given by a member of any one profession, but rather by the person who has the best skills and who is in the best position to provide long-term care and counselling. This may be a professional in the primary care situation (social worker, GP, district nurse), if he/she is adequately supported through opportunities for discussion with colleagues with experience of the condition.

In 1981 Harper *et al* published some results of a prospective study of relatives at risk of HC in South Wales. They demonstrated that, coinciding with the introduction of a systematic non-intensive genetic counselling and family support programme, a pronounced fall in the number of births at risk occurred. This contrasted with stable levels before the introduction of the programme. Further support for the effectiveness of even less intensive genetic counselling comes from a smaller study by Carter *et al* (1983).

The services mentioned are very rarely provided elsewhere. Stern & Eldridge (1975) found that medical personnel were cited as the best source of information in only 25% of respondents. Martindale & Yale (1983) found that genetic counselling was rarely offered to those at risk.

The evidence in this paper suggests that a variety of anxieties are aroused in professionals who have contact with both those at risk of HC and those with the disease and that these anxieties inhibit the professional from providing basic counselling services—this mirrors or replicates the difficulties of the families. Therefore, the professionals play a major part in the vicious circle that perpetuates the disease. My findings are similar to those of Britton (1981) who also clearly describes how the pattern of professional care given to other troubled families often unwittingly replicates or mirrors the unacknowledged family problems.

Acknowledgements

My thanks to the many professionals with whom I have discussed counselling issues, to Richard Rusbridger for his help with the manuscript and to Heather Murphy and Daisy Lake for secretarial assistance.

Cerebral Ventricular Enlargement in Chronic Schizophrenia:
Consistencies and Contradictions

A. FARMER, R. JACKSON, P. McGUFFIN and P. STOREY

A study of cerebral ventricular size measured as ventricle to brain ratio (VBR) using computerised tomographic brain scan in chronic schizophrenics provided no support for suggestions that there are significant differences between patients who fall into different clinical subtypes. We found no significant difference in VBR between patients with and without a family history of schizophrenia or between those with or without paranoid symptoms. Applying Crow's classification, contrary to expectations, Type 1 patients had significantly larger ventricles than those with 'mixed' symptomatology (both Type 1 and Type 2 features). We also applied a variety of operational criteria which attempt to define schizophrenia as a whole: of these only Schneider's first-rank symptoms (FRS) yielded conclusive results — FRS-positive patients had significantly larger mean VBR than those without such symptoms. Previously, it has been suggested that ventricular enlargement is more closely associated with 'negative' than with 'positive' symptoms.

Although earlier studies employing lumbar air encephalography produced inconsistent results (Jacobi & Winkler, 1927; Storey, 1966), recent computerised tomographic (CT) scan studies of chronic schizophrenia have been in substantial agreement. Following the first reports by Johnstone *et al* (1976) and Weinberger *et al* (1979) that a proportion of chronic schizophrenics, compared to controls, have enlarged cerebral ventricles, a number of other groups (e.g. Andreasen *et al*, 1982; Nasrallah *et al*, 1982) have confirmed this finding. The percentage of patients with such abnormalities has varied across studies but schizophrenic patient groups consistently show a larger average ventricular size than controls (*Lancet*, 1982), such that this may now be regarded as probably the most replicable biological feature which investigations of the condition have yet revealed.

There is now little dispute about the repeatability and veracity of the finding, but the explanation of ventricular enlargement in schizophrenia is a more contentious issue. The first studies were quickly followed by suggestions that CT scan abnormalities resulted from treatment of schizophrenia or prolonged stays in hospital (Jellinek, 1976; Marsden, 1976). However, subsequent investigations failed to support such a view (Weinberger *et al*, 1979; Tanaka *et al*, 1981). Therefore, most recent interest has centred on more optimistic hypotheses that CT scan abnormalities can tell us something about the aetiology and pathogenesis of schizophrenia, and do not merely reflect secondary consequences of the condition or its treatment.

One of the most provocative hypotheses has been that Johnstone *et al*, 1978). Their observation that ventricular enlargement appeared to be associated with 'negative' clinical features and a degree of cognitive impairment led to the suggestion that CT scan abnormalities provide the structural basis for the 'dementia in dementia praecox'. Subsequently, Crow (1980) proposed that schizophrenia could be divided into two syndromes — a Type 1 characterised by positive symptoms, good response to neuroleptics and probably resulting from abnormalities in brain dopaminergic systems, and Type 2 in which negative symptoms predominate, where response to neuroleptics is less satisfactory and where there is an association with cerebral ventricular enlargement. It was also suggested that in the Type 2 syndrome, ventricular enlargement might be associated with cognitive impairment. Unfortunately, a recent study by members of the same group (Owens *et al*, 1985) failed to show a relationship between ventricular size and cognitive abnormalities. Furthermore, Crow (1980) did not suggest that the two subtypes were necessarily distinct and non-overlapping. Nevertheless there remains considerable interest in such a classification scheme as a starting point for achieving a better understanding of the aetiology of schizophrenia and for deriving an appropriate rationale for the prescription of drugs.

An alternative aetiologically based classification has been put forward by Murray *et al* (1985): the argument is that a genetic contribution is the best established aetiological factor in schizophrenia (Gottesman & Shields, 1982) but a substantial proportion of schizophrenics have no secondary cases among their relatives. In identical twins discordant for schizophrenia, schizophrenic probands have significantly larger ventricles than the unaffected co-twins and there is a marked tendency for large ventricles to be associated with absence of family history in first-degree relatives (Reveley *et al*, 1984). It was therefore suggested that schizophrenia can be subdivided into a familial form, with normal cerebral ventricles and a presumed genetic aetiology, and a 'non-genetic' or sporadic form, associated with absence of genetic loading, enlarged cerebral ventricles and environmental insult to the brain, e.g. perinatal trauma (Murray *et al*, 1985).

Yet another group were unable to find an inverse relationship between presence of family history and enlargement of cerebral ventricles (Nasrallah *et al*, 1982) but did suggest that CT scan abnormalities might be associated with a more 'traditional' subtypology. The division of schizophrenia into hebephrenic and paranoid categories is notoriously imprecise and unreliable but Tsuang & Winokur (1974) have produced operational definitions of hebephrenic, paranoid and 'undifferentiated' schizophrenic subtypes which greatly improve interrater reliability (McGuffin *et al*, 1984). Applying Tsuang & Winokur (1974) criteria, Nasrallah *et al* (1982) found an association between ventricular enlargement and the paranoid category.

In our study on the CT brain scan appearances of chronic schizophrenics, we considered that each of these systems of the sub-classification merited further attention. However, a further problem is that of how to define schizophrenia as a whole. Operational diagnostic criteria provide a potential 'remedy for diagnostic confusion' (Kendell, 1975) for biological research in schizophrenia but there are now many systems of diagnosis available which show poor agreement one with another (Kendell *et al*, 1979). In the face of such difficulties, Kendell (1983) has suggested a 'polydiagnostic' approach, in which a range of commonly used definitions of schizophrenia are applied to the same set of patients, and the results analysed separately for each. There are two arguments in favour of this. Firstly, no clear-cut and conclusive method exists of deciding whether one set of criteria is 'more valid' than another. Secondly, a polydiagnostic scheme may help decrease disparities in the results of different investigators: (e.g. where investigator 'A' using criteria 'X' produces findings which are at odds with those of investigator 'B' using criteria 'Y'). We therefore decided to assess our patients using an operational criteria checklist composed of items extracted from a variety of commonly used operational diagnostic criteria for schizophrenia and which facilitates polydiagnostic investigation while preserving a satisfactory level of inter-rater reliability (Farmer *et al*, 1983; McGuffin *et al*, 1984).

Subjects and methods

Subjects

Thirty-five patients with a hospital diagnosis of schizophrenia (ICD-295) were selected as representing a series of 'typical' cases of chronic schizophrenia, requiring continued neuroleptic medication to ameliorate or prevent recrudescence of symptoms. All underwent computerised tomographic (CT) brain scanning using a 1010 EMI CT Scanner. The mean age at scan was 37.5 years (s.d. 9.3 years, range 22–57 years). The mean length of illness was 13 years (range 4–22 years).

Clinical assessment and diagnosis

Each subject's age at onset of illness (defined as date of first psychiatric onset) and age at scan was recorded. Duration of illness was calculated as the difference between these two dates. An independent investigator, blind to ventricular size measurements, interviewed the patient and at least one close relative informant to establish the presence or absence of a family history of schizophrenia in first-degree relatives. Where possible, hospital notes of relatives were obtained and examined to confirm diagnosis.

Our operational diagnostic criteria checklist was completed on every patient. This was an expanded version of one previously described (Farmer *et al*, 1983; McGuffin *et al*, 1984), which has been shown to have good item by item inter-rater reliability. The checklist (Appendix 1) was completed for each subject from detailed case records of good standard, which included a personal interview with at least one of the authors. The checklist was then scored dichotomously, as previously described — '0' if the item was absent and '1' if ever present. Where there was dubiety about presence or absence of particular checklist items, the patient was re-interviewed by A. E. F. The checklist data were entered into a computer programme SORT to produce a variety of operational definitions of schizophrenia (Schneider, 1959; Feighner *et al*, 1972; Spitzer *et al*, 1978; Carpenter *et al*, 1973) as previously described (McGuffin *et al*, 1984). In addition, the checklist was expanded slightly, enabling the DSM-III definition to be applied (American Psychiatric Association, 1980) (see Appendix 1). Two of us (A. E. F. and P. McG.) were able to achieve very good inter-rater reliability for DSM-III criteria, using the expanded checklist on a separate series of 20 consecutive admissions with psychotic disorders. ($K = 0.840$, $P = 0.00005$).

Subtyping of the patients into hebephrenic, paranoid and 'undifferentiated' categories was also derived from the checklist scores as previously described (McGuffin *et al*, 1984). In addition we applied a more recently derived method of categorising schizophrenics into categories which we have called 'H Type' (hebephrenic-like) and 'P Type' (paranoid-like) (Farmer *et al*, 1984). Lastly, we wished to divide our patients according to the scheme suggested by Crow (1980) descriptions were cast in an operational format and with his helpful advice we arrived at checklist-based algorithms enabling the separation of schizophrenic patients into Type 1, Type 2 and 'mixed' categories (see Appendix 1). Again we were able to establish excellent inter-rater agreement ($K=0.93$, $P=0.00001$) using a separate consecutive series of admissions.

Assessment of CT scans

The maximum ventricular-brain ratio (VBR) was measured for each scan using a semi-automated method (Reveley, 1985) in which the VBR is measured on the slice with the largest ventricular area. Pixels with a value of 0–25 Hounsfield Units (HU) are considered to represent areas of cerebrospinal fluid (CSF) and those with values from 0–99 HU represent areas of brain plus CSF. A computer count is made of pixels in the ventricular area with a value of 0–25 and of the total number of pixels within the inner table of the skull with a value of 0–99. The VBR (maximum slice) is the ratio (× 100) of these counts.

Results

Mean VBR was 5.88 (s.d. 3.16, range 1.0–15.2). The distribution was positively skewed (skewness 0.85) although when the square root transform for VBR was taken an acceptable Gaussian distribution resulted. Square root transformation of the VBR was therefore used in subsequent analyses. Mean root VBR for 25 male subjects was 2.39, and for 10 female subjects was 2.08. There was no significant difference in ventricular size between the sexes ($t=-1.22$, $P=0.11$).

There was no significant correlation between VBR and age of illness onset, age at scan or length of illness ($r=0.15$, 0.13 and 0.01 respectively). Similarly, there was no significant difference in VBR between six (17%) family history-positive subjects and 29 (83%) subjects who had no family history of schizophrenia in first-degree relatives (mean root VBR, family history-positive subjects = 2.17, family history-negative subjects = 2.33; $t=-0.49$, $P=-0.31$).

Table I gives the mean square root VBR and number of subjects in each category for five operational definitions. Schneider's and DSM-III provide dichotomous diagnoses (i.e. 'positive' or 'negative') and non-paired *t*-tests were carried out to compare mean root VBRs for each group. Schneiderian first-rank symptom-positive subjects were shown to have significantly larger mean ventricular size than first-rank symptom-negative subjects ($P=0.008$). However, DSM-III 'positive' cases were not significantly different from DSM-III 'negative' subjects.

Feighner's, Spitzer's and Carpenter's operational criteria provide a grading of diagnosis. Feighner classifies into 'definite', 'probable' and 'negative' categories, Spitzer into 'broad', 'narrow' and 'negative', and the Carpenter system provides '5-cut off', '6-cut off' and 'negative' categories. One-way analysis of variance was carried out to compare

TABLE I

				One-way analysis of variance				
Operational definition	*No. of subjects*	*Mean root VBR*	*Source*	*Sum of squares*	*d.f.*	*Mean square*	*F Ratio*	*P*
Feighner								
Negative	8	2.39	Between	3.38	2	1.69	4.29	0.02
Probable	10	1.82	Within	12.58	32	0.394		
Definite	17	2.54						
Carpenter								
Negative	16	2.13	Between	1.12	2	0.59	1.20	0.31
5 cut off	10	2.32	Within	14.84	32	0.46		
6 cut off	9	2.57						
Spitzer								
Negative	6	3.42	Between	0.65	2	0.32	0.68	0.51
Broad	1	1.50	Within	15.31	32	0.48		
Narrow	28	2.30						

Operational criteria		*No. of subjects*	*Mean root VBR*	*Non paired t-test*		
				T	*d.f.*	*P*
Schneider	Negative	15	1.99	2.53	33	0.0083
	Positive	20	2.54			
DSM-III	Negative	5	2.46	−0.57	33	0.29
	Positive	30	2.27			

mean root VBR for each group, for each of the three definitions. The results for Spitzer's and Carpenter's criteria were not significant. Feighner's 'definite' criteria showed significant difference between groups, but Table I shows that the distribution of mean root VBRs is somewhat odd, in that Feighner 'probable' subjects have the smallest mean root VBR, while Feighner 'negative' subjects are intermediate between these two.

Table II shows the number of subjects and mean root VBR for each subtypology. There proved to be no patients of the pure Crow Type 2, using the operational version of the Crow classification. Tsuang & Winokur non-paranoids, Crow Type 1 and Farmer H-type have the largest mean root VBR (2.41, 2.50 and 2.46 respectively) while Tsuang & Winokur paranoid, Farmer P-type and Crow mixed type have the smaller mean root VBR 1.96, 2.13 and 2.09 respectively). Only in the case of the Crow subtypology does the difference in mean root VBR attain statistical significance ($P = 0.04$); however, it is noteworthy that this is in the opposite of the expected direction in that Type 1 patients have a larger mean VBR than do Type 2 patients.

Discussion

Our aim was not to repeat the now well replicated finding that a proportion of schizophrenic patients show enlarged lateral cerebral ventricles, but rather to examine in detail the clinical features which may be associated with ventricular size, in an attempt to establish whether certain symptoms or clusters of symptoms distinguish patients with and without ventricular enlargement. In particular, we were keen to re-assess the claims that certain subtypologies show a relationship with ventricular size. We also aimed to discover whether any of the commonly used and competing operational diagnostic systems offered significant advantage in detecting a form of schizophrenia with a high rate of CT brain scan abnormality.

TABLE II
Ventricular enlargement and subtypes of schizophrenia

		No. of cases	*Mean root VBR*	*P*
Farmer	H-type	18	2.46	N/S
	P-type	17	2.13	(*t*-test)
Crow	Type I	18	2.50	
	Mixed	17	2.09	0.04
	Type II	0	—	(*t*-test)
Tsuang & Winokur (all subjects)	Hebephrenic	6	2.65	NS
	Paranoid	10	2.21	
	Undifferentiated	19	2.24	(Analysis of variance)
Feighner's subjects ($n = 27$)				
Tsuang & Winokur	Non-paranoid	19	2.41	NS
	Paranoid	8	1.96	(*t*-test)

In common with previous groups we obtained a positively skewed distribution of VBRs in our schizophrenic patients, but taking the square root of the results transformed the data to normality and enabled us to use parametric statistics in our analysis. There was no significant correlation between root VBR and age of onset or duration of illness. There was only a small and non-significant correlation between root VBR and age at scan but this is perhaps not surprising in view of the comparative youth of our sample (mean age 37.5 years, maximum age 57 years).

We found no significant difference between the mean VBRs of patients with or without a positive family history of schizophrenia. We thus found no support for the sporadic/familial classification scheme proposed by Murray *et al* (1985). It seems unlikely that our lack of significant difference between the family history-positive and -negative groups is simply due to a Type 2 error and small sample size, since there is not even a trend towards larger cerebral ventricles in the family history-negative group. Indeed, it is the family history-positive schizophrenics who have a slightly larger mean VBR. The division of schizophrenic patients into 'family history-positive' and 'family history-negative' groups is a difficult and unsatisfactory exercise in a number of respects. Firstly, some authors (e.g. Reveley & Chitkara, 1985) take 'family history-positive' to mean a family history of any major psychiatric disorder. However, since the familial diathesis in schizophrenia appears to be fairly specific for schizophrenia and schizophrenia spectrum disorders (Gottesman & Shields, 1982), it seems better to restrict the term 'family history-positive' to those patients who have secondary cases of schizophrenia in their family. Secondly, family history varies according to the quality of available information and the reliability of informants: certainly in our sample we have somewhat more complete information on some families than others. However, since family history was obtained 'blind' to CT scan results, it is unlikely that any bias could have been introduced which would lessen our chance of finding a negative family history-enlarged VBR association. Although one recent study (Turner *et al*, 1986) does support the findings of Reveley *et al* (1984), it is worth noting that most others (Nasrallah *et al*, 1982; Owens *et al*, 1985), in common with ourselves, do not.

On applying the operational checklist version of Crow's (1980) criteria, we were unable to find any pure Type 2 patients. However, nearly half of our subjects (17 out of 35) fell into the 'mixed' category, showing both Type 2 and Type 1 features. Unexpectedly again, it was the pure Type 1 patients who had the larger mean VBR, with the difference between the two groups (transformed data) being significant at the $P=0.05$ level. It could be argued that the version of the Crow (1980) criteria applied here, although providing good inter-rater reliability, is somewhat oversimplified and we had no specific information about cognitive impairment. The Northwick Park group (Owens *et al*, 1985) and a recent study from Oxford (Kolakowska *et al*, 1985) found no relationship between lateral ventricular size and cognitive impairment. However, it may be that other signs of CNS dysfunction, for example the presence of abnormal movements, are associated with enlarged cerebral ventricles (Owens *et al*, 1985) and such features might properly be incorporated into a revised version of the Type 2 syndrome definition (Crow, 1985).

Our third set of subtypologies were more closely related to traditional categories. Tsuang & Winokur (1975) criteria were applied but our data failed to reveal any significant difference between the hebephrenic, undifferentiated and paranoid categories in respect of ventricular size. Once again, the direction of our findings was the reverse of previously published results. Nasrallah *et al* (1982) found that paranoid schizophrenics had significantly larger ventricles than those who were not of the paranoid subtype. In our series it is the non-paranoid patients who have the slightly larger mean VBR and this applies whether we take the patient group as a whole or only the subset of patients who fulfill the Feighner (1972) criteria for schizophrenia (the latter being the way that Tsuang & Winokur (1975) originally suggested that their criteria be applied). We also used a method of subtyping devised by Farmer *et al* (1984), which although based on multivariate statistical analysis, consists of categories which are somewhat similar to the classical hebephrenic/paranoid classes. There was no significant difference between the groups, but again the H-Type or hebephrenic-like patients showed a slightly larger mean VBR than those of the P-Type or paranoid-like subgroup.

Finally, we examined the VBRs in our patients after classifying them according to a variety of operational diagnostic criteria (Schneider, 1959; Carpenter *et al*, 1973; Feighner *et al*, 1972; Spitzer *et al*, 1978; American Psychiatric Association, 1980). Only the criteria of Feighner *et al* (1972) and Schneider's first-rank symptoms (1959) yielded results which were significant. The Feighner classification allows the separation of patients into definite, probable, and negative (non-schizophrenic) categories. A one-way analysis of variance of root VBR yields significant differences within these groups but the findings are somewhat odd, in that the patients classified as Feighner 'probable' have a lower mean root VBR than the 'negative' or 'definite' groups, whereas, if we were to postulate that the Feighner definition provided a grading either of severity or of certainty of diagnosis, we might have expected the 'probable' category of patient to have a mean VBR which was intermediate between that of the 'negative' and the 'definite' categories. The findings regarding the Schneider criteria are more straightforward, in that there is a highly significant difference between those patients exhibiting first-rank symptoms and those who do not, with the Schneider 'positive' patients having the larger VBRs. Even if we apply a conservative correction factor and multiply the t value by the number of different operational systems used, the difference between the Schneider-positive and Schneider negative patients remains significant at the $P=0.04$ level. This finding is of interest in that several other groups have suggested that large ventricular size is most commonly associated with negative symptoms (Andreasen & Olsen, 1982; Gross *et al*, 1982; Kling *et al*, 1983; Kemali *et al*, 1985; Williams *et al*, 1985) or a Type 2 cluster of symptoms. Here, we have found that it is those patients with classical positive symptoms and those who fall into a Type 1 category who have the larger ventricles.

The subjects described here are in no way an unusual group and were selected specifically as a representative sample of patients with chronic schizophrenia. In the absence of a control group we can make no authoritative statements about which of them are 'normal' or 'abnormal' with regard to ventricular size, and even with access to acceptable controls such separations are somewhat arbitrary (Reveley, 1985). The mean and range of the VBRs in the patients reported here are, however, similar to those in previously described series of schizophrenic patients. Our focus of interest has been entirely upon within-group differences but our analyses provide no support for a consistent relationship between ventricular size and any of a range of clinical subtypes. Our most significant and quite unexpected finding is that in this series ventricular size is associated with the presence of positive symptoms. Inconsistencies and contradictions regarding the clinical features associated with ventricular size are present throughout the recent literature, and it is possible to speculate that technical differences in CT scanning and measurement, and differences in diagnostic criteria or the way that they are applied, play some part. A more fundamental problem may be that most workers have sought to

Coding algorithms[1] for Crow subtypology

Crow Pure Type I	A, B and C required A. One of 26 to 44=1 B. 23=0 C. 20=0
Crow Pure Type II	A, B and C required A. One of 20=1, 22=1, 23=1 B. 26–44=0 C. 48=0
Crow Mixed Type	A and B required A. One of 26 to 44=1 B. One of 20=1, 22=1, 23=1

B. 2 and 3=<45
C. 47=1
D. One of 27 to 32, 36 to 39, 41 to 44=1 OR one of 18, 19, 20=1 AND One of 15, 16, 22, 23, 24 26, 35, 40=1

NB Coding algorithms for all other operational definitions previously published (McGuffin *et al*, 1984, Farmer *et al*, 1984)

define categories of patients which differ with respect to a continuous measure of ventricular size such as VBR. No investigators have claimed bi-modality in the distribution of ventricular size and so we might pose the question whether any separation into discrete categories is warranted. However, the presence of bi-modality in itself may be misleading (Murphy, 1964) and a more rational approach to defining subpopulations within schizophrenia with respect to ventricular size might be to carry out an analysis of VBR in patient samples to discover whether the distribution can be more satisfactorily explained by the mixing of two or more curves. The general approach has been outlined (in a somewhat different context) by Everitt (1981) and would seem to be warranted here.

The Scottish First Episode Schizophrenia Study

I. Patient Identification and Categorisation

THE SCOTTISH SCHIZOPHRENIA RESEARCH GROUP

Forty-nine first episode schizophrenics were identified and considered to be representative of the parent schizophrenic population. Patients were rated before treatment with the Present State Examination. Findings are presented with regard to Catego classes, prevalence of first rank symptoms, conformity to ICD diagnoses, Feighner and Research Diagnostic Criteria and presence of a depressive syndrome. Physical examination revealed isolated neurological signs; in addition two neuroleptically naive patients had abnormal involuntary movements.

In recent years the treatment of schizophrenia has changed considerably, first because of widespread use of neuroleptics as maintenance therapy, and secondly as a result of greater awareness of patients' social needs; most schizophrenics are now cared for throughout most of their illness in the community.

In view of these developments a cohort of first episode schizophrenics has been identified. It is intended to follow them prospectively for 5 years, with detailed assessment at the time of first hospital admission, and at 1, 2 and 5 years after the first admission. The project aims to chart the clinical course of the illness, to compare and contrast different methods of categorising schizophrenia, to assess the efficacy of drug treatment, to examine intellectual and radiological changes, and to measure the impact of the illness on patients' relatives.

This series of papers examines the first episode of illness and this first paper describes the identification and categorisation of patients.

Method

All members of the Group for the Study of Rehabilitation and Community Care of the Scottish Division of the Royal College of Psychiatrists were invited to participate. Consultant psychiatrists from seven hospitals expressed interest and eventually patients from four hospitals entered the study over 2 years. The study was approved by the relevant hospital ethical committees.

Patient identification and categorisation

The criterion for entry was the responsible clinician's diagnosis of patients admitted to hospital with a first episode of schizophrenia. The patient's age, sex, social class, marital status, domiciliary status, and family history of psychiatric illness were recorded. A full medical history was taken and physical examination including the Northwick Park Brief Neurological Assessment (Owens & Johnstone, 1980) and Abnormal Involuntary Movements Scale (AIMS) (United States Department of Health, Education and Welfare, 1976) carried out.

As the study drew on patients from several centres attention had to be paid to comparability of symptom detection and clinical assessment among clinicians taking part. For this reason, within the first week of admission, patients were interviewed using the Present State Examination (PSE) (Wing *et al*, 1974). Several training sessions were held before and during the study. Because of continuing interest in diagnostic criteria for schizophrenia and in their usefulness in predicting outcome (Brockington *et al*, 1978) Feighner and Research Diagnostic Criteria (RDC) were also applied (Feighner *et al*, 1972; Spitzer *et al*, 1978) using information from the PSE interview. The presence of first-rank symptoms as described by Schneider (1974) was also assessed. Finally, the presence of a depressive syndrome was assessed by ignoring schizophrenic exclusion criteria within the RDC description of major depressive illness.

Results

Patient identification

Forty-nine patients entered the study. Knowledge of hospital catchment area populations, inception rates for schizophrenia (Cooper, 1978) and first admission rates in Scottish mental hospitals (Eagles & Whalley, 1985) suggested approximately half of first episode schizophrenics admitted to the participating units entered the study. Of the 49 patients, 47% were male, 53% female. Demographic and social data are shown in Table I. Males tended to be younger and more had never married ($\chi^2 = P < 0.05$). Feighner criteria applied to patients' relatives' case records suggested that four patients (8%) had a first degree relative with schizophrenia.

Twenty per cent ($n = 10$) had a history of possible neurological dysfunction (head injury in eight patients,

2. As assessed by father's most recent occupation

epileptic seizure aged 15 in one and polio as a child in another). Five patients reported sporadic cannabis use; a further patient may have taken LSD one year before admission.

Twenty per cent ($n=10$) had abnormal findings on neurological examination: equivocal or definitely abnormal plantar responses ($n=4$), equivocal difficulty in co-ordination ($n=2$), weakness in lower limbs ($n=1$), diminished tone in lower limbs ($n=1$) and increased ankle and knee jerks ($n=1$). The tenth patient with a history of polio had a mixture of neurological signs: A further three patients had abnormal involuntary movements as assessed by the AIMS global rating—one minimal, one mild and one severe; the two latter had had no antipsychotic medication in the 3 months before admission.

Patient categorisation

Catego system

Catego analysis of the PSE revealed three diagnostic groupings. These were Class S+, which contains central schizophrenic symptoms (disorders of possession of thought, delusions of control and voices discussing patient in third person or commenting on thoughts/actions), Class P+, a paranoid psychosis containing other than first-rank delusions and non-auditory hallucinations, and Class O+, other psychoses where the chief features are catatonic symptoms and behaviour which indicates hallucinations. Thirty-four patients could be given Catego classes with certainty (S+ =30, P+ =1, O+ =3) corresponding to ICD-9 codings of 295.3, 297.9 and 296.2 respectively (WHO, 1978). For 15 patients Catego classification was uncertain (S? =3, P? =5, O? =7).

First-rank symptoms

Of the 49 patients, 26 (52%) had one or more first-rank symptoms. The most common was of delusions of control or of alien forces penetrating the mind, with 13 (26%) patients positively rated, followed by delusional perception (24%), diffusion of thought (24%), and auditory hallucinations in the third person (22%).

American diagnostic criteria

There were 33 definite and nine probable cases of schizophrenia diagnosed by RDC. This contrasts with 12 definite and three probable cases diagnosed by Feighner's criteria. Of the 34 patients who did not fulfil the Feighner criteria, 31 (91%) failed as they had not shown symptoms for at least 6 months.

Presence of a depressive syndrome

When RDC for major depressive disorder were used but criteria excluding patients exhibiting schizophrenic symptoms were ignored, 11 patients (22%) showed a clear-cut depressive syndrome.

Other symptomatology

Other findings culled from the PSE ratings demonstrate the degree to which the study population was distressed and disturbed. Fifty six per cent scored positively on three or more anxiety items and 42% were rated as showing social withdrawal. Almost half expressed irritability, and 18% had attempted suicide. Nearly a quarter were rated as being hostile or suspicious. Over half showed blunted or incongruous affect and a quarter had incoherent speech. There was impairment of insight in 90%. In a third of interviews, the rater noted serious doubt about the adequacy of the interview for rating purposes.

Discussion

The number of patients who entered the study over 2 years was small but was concentrated in four units. As probably about half of all first episode schizophrenics admitted to these units entered the study and as we have no reason to believe there was any systematic bias, the results are likely to be representative of the parent group of first episode schizophrenics. Half the patients were in Social Classes IV and V or were unemployed; perhaps downward social mobility has already begun by the first episode, as suggested elsewhere (Goldberg & Morrison, 1963).

The reliability of information obtained about previous neurological dysfunction is uncertain but a considerable number of patients reported previous head injury. Neurological assessment detected isolated abnormalities in 20% but in only one patient, with a history of polio, were there widespread signs. The significance of the neurological examination is as yet unclear; 'soft' neurological signs can be found in 10% of normal children (reviewed by Shaffer, 1978). If signs persist at future examinations, then they may indeed suggest a significant neurological deficit now believed to exist in chronic schizophrenics (reviewed by Manschreck & Ames, 1984).

If a rating of mild on the AIMS global scale can be taken as definite evidence of abnormal involuntary movements, then two patients had this disorder. Controversy about the aetiology of such movements in schizophrenia continues but as both patients were almost certainly neuroleptically naive, it is most unlikely they were drug induced. Abnormal movements have long been described in schizophrenia (Kraepelin, 1919).

With regard to the PSE, concern about the adequacy of a third of interviews for rating purposes might seem to cast doubt on the reliability of the findings. However, there is ample evidence that this was a disturbed psychotic group of patients. The problem lies in the difficulty of reconciling the cerebral and reliable style of the PSE with the incoherence of psychosis.

The distribution of patients into the three Catego classes is broadly similar to that found in the WHO International Pilot Study of Schizophrenia (WHO, 1973; Wing *et al*, 1974). This suggests that clinicians in the present study entered patients as suffering from schizophrenia on the basis of a clear-cut illness. This is especially true given that the threshold of rating for symptoms in the PSE is high, compared to normal clinical practice.

The proportion of patients exhibiting one or more first-rank symptoms is in keeping with that found in earlier studies (reviewed by Lewine *et al*, 1982). However, there was a difference in frequency of particular symptoms between the present study and that of Lewine *et al*; delusional perception (primary delusions) was more common in the former study, disorders of possession of thought more common in the latter. This may be due in part to the fact that the latter population was an unselected group of schizophrenic admissions, and not first episode patients; primary delusions may become overlaid during subsequent admissions. The difference between the two populations for disorders of possession of thought is less easily explained, but perhaps bears out comments made by Mellor (1982) who criticised a facile approach to the rating of first rank symptoms and the attribution of too much weight to their presence for clinical diagnosis of schizophrenia.

Feighner's criteria are probably excessively strict; one study (Brockington *et al*, 1978) found only 10 out of 119 schizophrenic patients met the criteria; the results reported here would bear this out. While the RDC are less stringent, they are research criteria and would exclude almost a quarter of the study population, already shown to be clearly psychotic. This serves as a reminder that findings from a strictly defined research population may not be immediately generalisable to the clinical population. DSM III (American Psychiatric Association, 1980) is derived in part from these two sets of criteria, and is likely to reduce the number of patients diagnosed as suffering from schizophrenia (Mukherjee, 1983). The present Scottish evidence suggests it will be an excessive reduction.

The nature of 'depression' in schizophrenia has been debated recently (Johnson, 1981; Hirsch, 1982; Galdi, 1983). There is no doubt that symptoms commonly found in depressive illness occur in schizophrenic patients. In the absence of external validating criteria for the presence of depressive illness no study such as the present work can decide how often a 'proper' depressive illness has occurred. However, when criteria required to be met before depressive illness can be diagnosed in other contexts are applied, only a few patients meet the criteria. These patients had not yet started treatment and therefore there is no question of a pharmacogenic depressive process.

In conclusion, it can be said that the patients entering the study were ill, would have been recognised as such by clinicians, and would have been diagnosed as suffering from schizophrenia.

The Scottish First Episode Schizophrenia Study

II. Treatment: Pimozide Versus Flupenthixol

THE SCOTTISH SCHIZOPHRENIA RESEARCH GROUP

In a randomised double-blind study, 46 first episode schizophrenics were given pimozide or flupenthixol for up to 5 weeks; the mean daily dose at the end was 18.8 mg pimozide and 20 mg flupenthixol. There were no significant between-drug differences in the effect on mental state or behaviour; positive schizophrenic symptoms responded to treatment, negative symptoms did not. Most patients required anti-Parkinsonian medication. Poor response was associated with 'organicity'. A switch to maintenance therapy after 5 weeks, the outcome of successful treatment and patient cooperation, was achieved in only 54%.

There was no relationship between plasma prolactin levels and severity of schizophrenic symptoms in unmedicated patients. Pimozide produced greater elevation of plasma prolactin. Plasma neuroleptic levels showed drug compliance was satisfactory throughout in only 54%.

Pimozide, a member of the diphenylbutylpiperidine group of neuroleptics has been used mainly as maintenance therapy in chronic schizophrenia (e.g. Falloon *et al*, 1978). Little attention has been paid to its possible antipsychotic effect in acute schizophrenics. There have only been four double-blind studies of pimozide in such patients all of which suggest it may be a useful anti-psychotic though two found it less effective than the comparison drug (Haas & Beckman, 1982; Chouinard & Annable, 1982; Pecknold *et al*, 1982; and Silverstone *et al*, 1984). The present study is the largest and most comprehensive to date as it examines not only pimozide's clinical efficacy but also plasma prolactin and neuroleptic levels and drug compliance. It compares pimozide with flupenthixol, a drug shown in a placebo controlled double-blind study to be an effective antipsychotic (Johnstone *et al*, 1978).

The study also examines the relationship in unmedicated patients between severity of schizophrenic symptoms and plasma prolactin levels, to investigate further the dopamine hypothesis of schizophrenia (Carlsson, 1977).

Method

Patients and medication

Of the 49 patients who entered the first episode schizophrenia study (see Part I), 46 took part in the drug study: 21 males, 25 females, mean age 30.6 years (range 16–68 years).

In the 3 months before hospital admission 26% had received small doses of thioridazine or chlorpromazine; the total dose ranged from 50–1400 mg. Up to 7 days after admission patients could receive droperidol for severe behavioural disturbance. Patients were then randomly and blindly allocated to receive in a double-dummy design pimozide or flupenthixol. The starting dose of both was 10 mg daily and could be increased to a maximum of 40 mg pimozide and 50 mg flupenthixol. Treatment lasted 5 weeks after which time, or before if patients had improved sufficiently, they were switched to maintenance therapy. If in the clinician's opinion a patient had not improved by then he was given in addition electroconvulsive treatment (ECT) or another neuroleptic. Also, patients did not receive maintenance therapy if there was no clear rise in plasma prolactin during treatment (see below).

During treatment with pimozide or flupenthixol, patients could receive droperidol for severe behavioural deterioration, an anti-Parkinsonian drug, procyclidine, and an hypnotic, temazepam.

Assessment

On admission to hospital, immediately before starting treatment with pimozide or flupenthixol ('Baseline') and then at weekly intervals, patients' mental state and ward behaviour were assessed by the Krawiecka and Wing Scales respectively (Wing, 1961; Krawiecka *et al*, 1977). One item on the Krawiecka Scale, 'affect', was divided into inappropriate and blunted affect. Parkinsonism and abnormal movements were also measured (Simpson & Angus, 1970; US Department of Health, Education and Welfare, 1976).

Blood samples were taken at regular intervals to measure plasma prolactin, pimozide and flupenthixol levels estimated by specific radioimmunoassay techniques (Prolk-PR commercial kit [CIS UK Ltd]; Michiels *et al*, 1975; FPT-RIA-200 commercial kit [IRE Ltd]).

Differences between the two drug groups were tested by independent t-tests; paired t-tests were used to measure differences within groups over time. Correlations between groups were measured by the Product Moment Correlation Coefficient. The χ^2 test was used to measure different frequencies in discrete categories.

Results

Patients on pimozide and flupenthixol were well matched. There were no statistically significant between-group differences in age and sex distribution, family history of schizophrenia, categorisation of schizophrenia, intelligence quotients, prevalence of neurological signs, and severity of illness at baseline, as measured by the Krawiecka and Wing Scales.

Of the 23 patients who received pimozide, 15 completed 5 weeks of treatment and a further three were switched to maintenance therapy before the end of 5 weeks. Three refused to continue with drug treatment; one discharged himself against medical advice; and one developed a skin rash. The mean daily dose at the end of week 5 was 18.8 mg.

Of the 23 patients who received flupenthixol, 17 completed 5 weeks of treatment and three switched to maintenance therapy before the end of 5 weeks. One patient was discharged well without any significant elevation in plasma prolactin level, one was discharged well but not given maintenance therapy as she left Scotland, and one discharged himself against medical advice. The mean daily dose at the end of week 5 was 20.0 mg.

Mental state (Figs 1 and 2)

In both pimozide and flupenthixol groups there was during the admission period a statistically significant reduction in Krawiecka total scores indicating an improvement in mental state ($t = 3.23$, $P < 0.01$ and $t = 2.51$, $P < 0.02$ respectively). Such improvement continued during drug treatment (baseline compared with subsequent weekly scores: t ranged from 3.67 to 7.99; P from <0.01 to <0.001). In both pimozide and flupenthixol groups, positive schizophrenic symptoms (inappropriate affect, incoherence, delusions and hallucinations) improved significantly during the admission period ($t = 3.40$, $P < 0.01$ and $t = 2.73$, $P < 0.02$ respectively) and drug treatment (t ranged from 3.02 to 7.32 P from <0.01 to $<0.0.001$). Negative symptoms (blunting of affect and poverty of thought) did not change in either group during admission or treatment periods. Non-schizophrenic symptoms did not change in either group during the admission period, but were significantly less when compared with baseline scores at the end of week 1 in the flupenthixol group ($t = 2.30$, $P < 0.05$) and week 5 in the pimozide group, ($t = 2.60$, $P < 0.05$).

There were no significant between-group differences on admission, immediately before, during or at the end of treatment in total, positive schizophrenic, negative schizophrenic, and non-schizophrenic symptom scores (independent t-tests).

Behaviour (Figs 1 and 2)

In both drug groups there was no significant change in total Wing scores during the admission period. In both groups there was a statistically significant reduction in scores during treatment indicating improvement in behaviour, evident in both groups by the end of week 2 (pimozide: $t = 3.56$, $P < 0.01$; flupenthixol: $t = 2.29$, $P < 0.05$). Embarrassing behaviour and social withdrawal had improved significantly by the end of week 2 in the pimozide group ($t = 2.99$, $P < 0.01$; $t = 2.55$, $P < 0.02$) and by weeks 1 and 3 in the flupenthixol group ($t = 2.19$, 2.57; both $P < 0.05$).

There were no statistically significant between-group differences at admission, immediately before, during or at the end of treatment in total, socially embarrassing and social withdrawal scores.

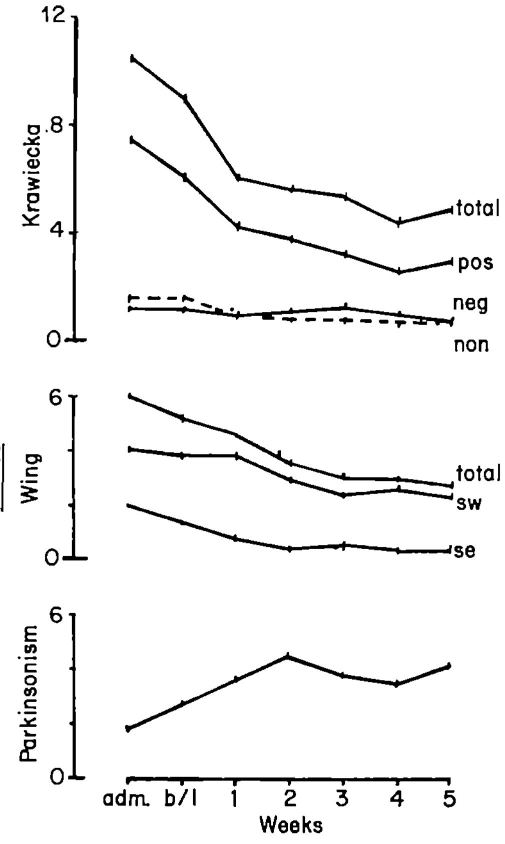

FIG 1. *Pimozide Group.* Weekly mean Krawiecka (mental state), Wing (behaviour) and parkinsonism scores. POS = positive schizophrenic symptom scores; NEG = negative schizophrenic symptom scores; NON = non-schizophrenic symptom scores; SW = social withdrawal scores; SE = socially embarrassing behaviour scores; Adm = admission; b/l = baseline.

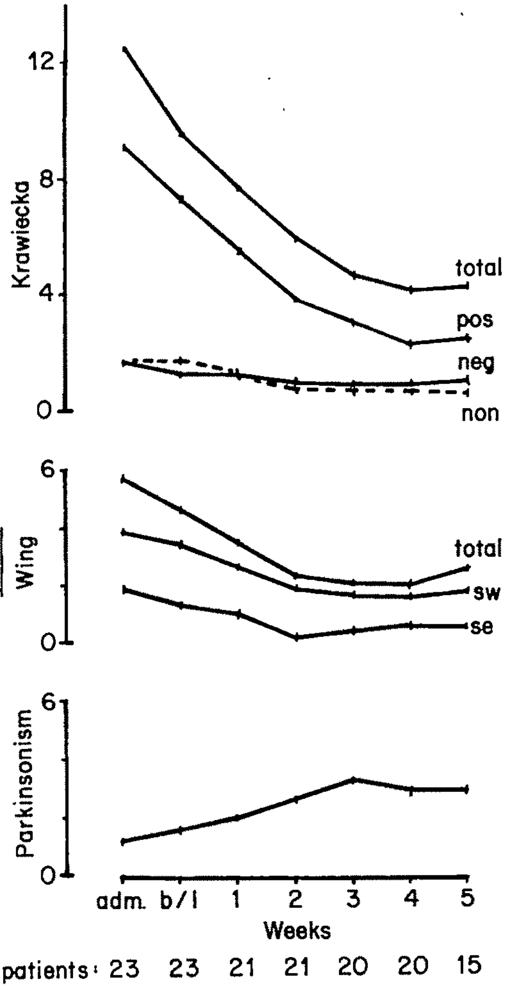

FIG. 2. *Flupenthixol Group.* Weekly mean Krawiecka (mental state), Wing (behaviour) and Parkinonism scores. POS = positive schizophrenic symptom scores; NEG = negative schizophrenic symptom scores; NON = non-schizophrenic symptom scores; SW = social withdrawal scores; SE = socially embarrasing behaviour scores; Adm = admission; b/l = baseline.

Parkinsonism (Figs 1 and 2)

Changes in Simpson and Angus scores are hard to interpret as many patients were quickly prescribed anti-Parkinsonian drugs (see below). In both groups there were no significant changes in the admission period. In the flupenthixol group there was a statistically significant increase in Parkinsonism ($t = 3.11$, $P < 0.01$) by the end of week 2, which persisted throughout the drug period. In the pimozide group scores rose during drug treatment but not significantly.

By the end of the first week of treatment, 57% of patients on pimozide and 35% on flupenthixol were receiving procyclidine; by the end of 5 weeks, these figures had risen respectively to 78% and 85%. There were no significant between-group differences in numbers of patients receiving anti-Parkinsonian medication (χ^2 test).

Abnormal movements

In the admission period three patients had abnormal movements as assessed by the Abnormal Involuntary Movements Scale (AIMS) (see Part I); these movements disappeared during treatment. One patient on flupenthixol and one on pimozide developed respectively mild and moderate movements during treatment.

Droperidol

In the admission period, 43% and 52% of patients in the pimozide and flupenthixol groups respectively required at least one dose of droperidol. Improvement in patients' mental state during this period was not due to droperidol as there were no significant differences between droperidol and non-droperidol groups in mental state scores, at admission or baseline. Numbers of patients receiving droperidol fell sharply during the weeks of treatment and in neither group were they ever greater than 20%. There were no significant between-group differences in numbers of patients requiring droperidol.

Plasma prolactin and neuroleptic levels (Fig. 3)

Virtually complete plasma prolactin and neuroleptic results were obtained in 12 patients on pimozide and 10 on flupenthixol. The pretreatment prolactin level was taken to be the mean of three levels—two during the admission period and one immediately before the administration of the first dose of pimozide or flupenthixol. Pimozide produced greater elevation of plasma prolactin, the level of which was significantly higher than in the flupenthixol group by the end of week 2 ($t = 2.29$, $P < 0.05$). There were no significant between-sex differences in plasma prolactin either at the end of week 1 or 5.

Product moment correlations between plasma prolactin, plasma neuroleptic, and neuroleptic dose were weakly positive but only occasionally reached statistical significance in some weeks when plasma neuroleptic levels were compared with dose and prolactin. Correlations were lowest between dose and plasma prolactin.

Compliance

In the 22 patients in whom virtually full pharmacokinetic data were available, compliance was estimated by examination of weekly neuroleptic levels. When a patient remained at the same dose level for more than 1 week, if subsequent neuroleptic levels were within 10% of the first level, compliance was 'good'. If a subsequent level was 10–50% lower than the first, compliance was 'doubtful' and, if it was less than 50%, it was 'poor'. Using these criteria, compliance in 54% of patients was good throughout the treatment period, doubtful on at least one occasion in 23% and poor on at least one occasion in 23%.

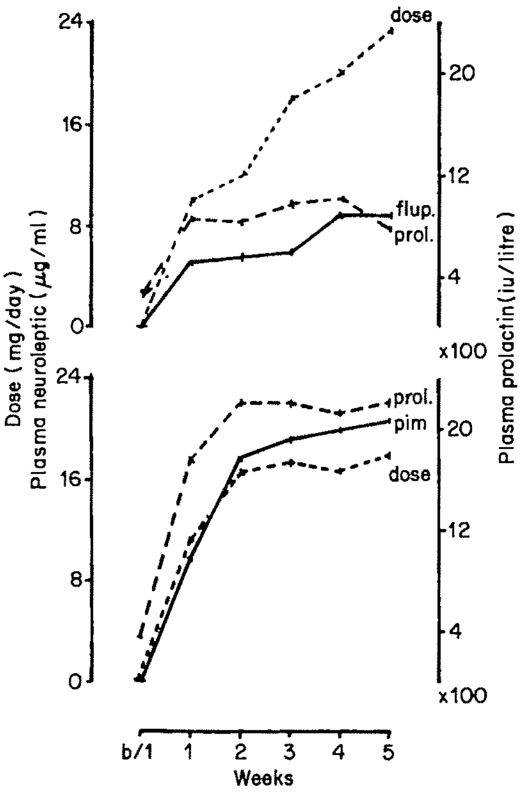

FIG. 3. Weekly mean neuroleptic dose, plasma neuroleptic level, and plasma prolactin level. The upper graph refers to the flupenthixol group, ($n = 10$) the lower to the pimozide group ($n = 12$). FLUP = plasma flupenthixol level; PROL = plasma prolactin level; PIM = plasma pimozide level; b/l = baseline.

Responders vs non-responders

At the end of treatment, patients were divided into three groups; these comprised 'responders' to pimozide or flupenthixol (63%) of whom 25 started but four refused maintenance therapy, 'non-responders' (17%) who received further treatment, either ECT or another neuroleptic, and 'non-completers', who did not proceed to maintenance therapy but could not clearly be said to be 'non-responders' such as those who were discharged prematurely against medical advice (20%). As results with pimozide and flupenthixol were broadly similar, the two neuroleptic groups were combined and 'responders' compared with 'non-responders'. The number of 'non-responders' was too small to produce statistically significant differences but the observation was that more 'non-responders' were male (63% *vs* 31%), and had neurological signs (50% *vs* 17%), a greater mean Progressive matrices/Mill Hill Vocabulary discrepancy (8 points *vs* 3 points) and higher mean negative schizophrenic score (2.1 *vs* 1.2). There was no relationship between lack of response and poor drug compliance.

Prolactin and schizophrenic symptoms

A small group of patients ($n = 9$) fulfilled the following criteria: they had a diagnosis of definite or probable schizophrenia, based on the RDC; had received no anti-psychotic medication in the 3 months prior to admission nor droperidol during the admission week; and had a baseline plasma prolactin level. There were no significant correlations between such prolactin levels and baseline scores on the Krawiecka scale, either total scores ($r = +0.04$) or positive schizophrenic symptom scores ($r = +0.12$).

Discussion

The study was not placebo controlled and no doubt non-drug factors contributed to patients' improvement; during the admission (pre-drug treatment) period there was a significant improvement in positive schizophrenic symptoms. It is unlikely, however, that there was no subsequent drug effect as commercial flupenthixol, used in the present study, contains 50% α flupenthixol, which has been shown to be more effective than placebo in acute schizophrenics (Johnstone *et al*, 1978).

Pimozide is an effective anti-psychotic in acute schizophrenia. It and flupenthixol are broadly similar in efficacy, especially in the speed of reduction of positive schizophrenic symptoms. Neither drug had any appreciable effect on negative schizophrenic symptoms.

The final mean daily dose of pimozide, 18.8 mg, was at the lower end of the dose range in other previously quoted controlled studies, 20–74.5 mg; the mean dose of flupenthixol, 20 mg, was just double that of α flupenthixol (9 mg) in the study quoted above. Probably one reason why clinicians did not prescribe higher doses was the rapid development of Parkinsonism which by the end of the study resulted in most patients in both groups receiving procyclidine.

Neuroleptic dose and plasma prolactin and neuroleptic levels correlated positively but weakly. Prolactin elevation was evident in both groups by the end of the first week but pimozide had a greater effect. This is of doubtful clinical significance as there is no clear relationship between plasma prolactin elevation and clinical efficacy (Kolakowska *et al*, 1980). Plasma neuroleptic estimations however enabled drug compliance to be assessed. In a bare majority of patients was compliance throughout the study period satisfactory. Perhaps the high prevalence of Parkinsonism was a contributory factor to doubtful or poor compliance as such side-effects have been shown in chronic schizophrenics to be associated with poor neuroleptic compliance (Van Putten, 1974).

The number of non-responders was small but 'organicity' as shown by neurological signs, greater performance/verbal discrepancy, and more negative symptoms was associated with a poor response.

The number of unmedicated patients in whom it was possible to correlate schizophrenic symptoms with plasma prolactin was also small, but the present study lends no support to the hypothesis that the schizophrenic process is mediated through dopamine over-activity. This is in contrast to previous work (Kleinman *et al*, 1982) which found an inverse relationship between positive symptoms and prolactin secretion but only in schizophrenics with normal computerised axial tomography (CAT) scans. Other work (Ferrier *et al*, 1984) found such a relationship to be weak. However, many other factors apart from dopamine can affect prolactin secretion.

It is noteworthy that for various reasons, especially lack of response and failure to cooperate, only 54% of patients could be started on maintenance therapy after 5 weeks. The course of the illness in both responders and non-responders after this first acute stage will be reported in later papers but it is already clear that we cannot be complacent about the present day treatment of first episode schizophrenia.

The Scottish First Episode Schizophrenia Study

III. Cognitive Performance

THE SCOTTISH SCHIZOPHRENIA RESEARCH GROUP

Cognitive performance in 46 first episode schizophrenics was assessed within 1 week of admission to hospital by Progressive Matrices, Mill Hill Vocabulary Scale, Block Design and Similarities subtests of the Wechsler Adult Intelligence Scale, and Digit Copying Test. Patients' intellectual performance was at a dull normal level, just within one standard deviation from the mean. There was an association between the presence of anxiety and depression and lower scores on psychological tests. Patients assessed by the Present State Examination as belonging to the 'uncertain psychosis' category performed more poorly.

Early studies of cognitive functioning in chronic schizophrenics (reviewed by Matarazzo, 1972 and Heaton *et al*, 1978), found no characteristic pattern which differentiated them from patients with organic brain disease. Variables other than intelligence were better at separating the diagnoses. More recent work, however, has found a link in long-stay chronic schizophrenic in-patients between age disorientation, neurological deficit and cognitive impairment (Crow & Stevens, 1978; Owens & Johnstone, 1980; Liddle & Crow, 1984). The few studies of cognitive functioning in acute schizophrenics (reviewed by Payne, 1960, 1973) found them to be duller than average. Payne's conclusion was that psychosis produced a degree of general impairment, which was related to the severity of the illness and was probably progressive if the patient did not recover. Recovery was accompanied by a considerable improvement in general intellectual functioning. Another study, not reviewed by Payne (Foulds & Dixon, 1962*a*,*b*; Foulds *et al*, 1962) concluded that all types of schizophrenics showed intellectual impairment of a reversible kind and that impairment occurred mainly between the onset of illness and first admission to hospital. Any further decrement was brought about by age and was not mediated by being in hospital nor related to length of illness.

A more recent review (Aylward *et al*, 1984) found pre-morbid deficits were more common in men, a trend contrary to Foulds' finding that male schizophrenics had significantly better scores on both Matrices and Mill Hill Vocabulary.

The present study describes the cognitive performance of patients experiencing a first episode of schizophrenia using tests which allow direct comparison with the study of Foulds and reviews of Payne and Aylward. The relationship between cognitive performance and various measures of psychopathology is also examined.

Method

Forty-six out of 49 first episode schizophrenic in-patients (see Part I) were tested within 7 days of admission. Three patients were not tested because of failure to cooperate; some patients did not complete all the test battery. The tests given were Progressive Matrices (Raven, 1938), Mill Hill Vocabulary Scale (Raven, 1948) and the Block Design and Similarities subtests of the Wechsler Adult Intelligence Scale (Wechsler, 1955). A Digit Copying Test (Gibson & Kendrick, 1979) which is only modestly correlated with intelligence was included as a simple test of speed in performance.

Differences between groups were tested by t-tests or analysis of variance as appropriate; differences between means in the latter were tested by Tukey's "honestly significant difference" procedure (Zar, 1984). Correlation between groups was measured by the product moment correlation coefficient.

Results

Table I shows the scores obtained on the tests; for Matrices and Mill Hill Vocabulary means and standard deviations are shown for raw scores and for WAIS-type IQ scores, whilst for Block Design and Similarities they are shown for subtest scaled scores and pro-rated performance and verbal IQ scores respectively. Taken together, the tests indicate that patients performed at a dull normal level just within one standard deviation from the mean. The mean performance on Digit Copying was slightly higher than the mean score of 98.4 obtained by Kendrick's normal old people but was much more variable, the standard deviation being twice that of normals. Women performed better than men on Similarities ($t=2.15$, $P<0.05$) but not on other tests; this sex difference on Similarities ceased to be statistically significant when the presence of Krawiecka negative symptoms was taken into account (see below).

Means, but not standard deviations, for age, Matrices score and Mill Hill Vocabulary score in 90 patients who had been in hospital less than one year at the time of testing were extracted from Fould's study. The present group and this short stay subgroup of Foulds did not differ in mean age or Matrices score but differed on Vocabulary; Foulds' subgroup scored higher. If the present standard deviation is taken as a reasonable estimate of the variability in Foulds' patients the difference between means is statistically significant ($t=3.97$, $P<0.001$).

The four intelligence tests correlated significantly with each other and all except Mill Hill Vocabulary correlated significantly with Digit Copying. The correlations ranged from +0.53 to +0.70 and are similar to those reported in test manuals.

Intellectual status was associated with the Catego class derived from the Present State Examination (Wing *et al*, 1974) (Table II). The mean test scores for the 'Uncertain Psychosis' class were lower than those for 'Definite Psychosis' and 'Possible Neurosis' classes. Analysis of variance showed that only Similarities failed to show a statistically significant difference in the three classes. Tukey's procedure showed that the Uncertain Psychosis group scored significantly worse than Possible Neurosis patients on Vocabulary, Matrices and Block Design and significantly worse than the Definite Psychosis group on Matrices, Block Design and Digit Copying. The Possible Neurosis and Definite Psychosis groups did not differ significantly on any of the tests. The Uncertain Psychosis group had more non-schizophrenic symptoms on admission as assessed by the Krawiecka scale (see Part II) than the other two groups (F=6.78; *d.f.* 2, 45; $P<0.003$).

There was no relationship between positive schizophrenic symptoms on admission as assessed by the Krawiecka Scale and intellectual performance and only Similarities was significantly associated with negative schizophrenic symptoms ($r=-0.43$, $P<0.01$). There was a clear association between non-schizophrenic symptoms, in the main anxiety and depression, and lower scores on psychological tests (r ranged from -0.30 to -0.52; P ranged from <0.05 to <0.01); only Matrices did not correlate significantly with such symptoms.

Patients with significant signs of Parkinsonism on admission, that is, a score of more than 3 on the Simpson and Angus Scale (Simpson & Angus, 1970)

TABLE I
Scores on cognitive tests

Test	*Number of patients*	*Raw scaled scores Mean*	*s.d.*	*IQ scores Mean*	*s.d.*

performed less well on Digit Copying ($t=4.87$, $P<0.001$) and the WAIS subtests of Block Design and Similarities ($t=2.33$, 2.53 respectively: both $P<0.05$); however, when account was taken of the very poor performance on Digit Copying, a series of partial correlations showed that correlations between Parkinsonian symptoms and the two WAIS subtests diminished to near zero.

Some patients had received small amounts of neuroleptics before admission and others droperidol during the first week after admission (see Part II); there were no significant differences in any of the psychometric tests between those who had such drugs and those who had no antipsychotic medication before assessment.

Discussion

The results suggest the intellectual performance of newly admitted schizophrenic patients was below average, to a degree consistent with the studies summarised by Payne and Aylward. Verbal performance was lower than that reported by Foulds, but the reason for this is not clear. There was no marked sex difference in test performance, which is at odds with the trend reported by Aylward and the findings of Foulds. Similarly, there was no strong link between cognitive performance and neurological state. Patients with Parkinsonian symptoms performed very poorly on Digit Copying, probably because of slowness in both thought and action. This impairment also showed itself on Block Design and Similarities but detailed partial correlation analysis showed the correlation was due to slowness rather than intellectual impairment.

Test performance showed interesting links with various mental state assessments. Almost all tests correlated with Krawiecka non-schizophrenic symptom scores, in the main anxiety and depression. Such general emotional upset is known to impair performance over a wide range of psychological tasks. Anxiety and depression were greater in the Uncertain Psychosis group. This might explain the difference between that category and the other two on cognitive assessment; perhaps emotional disturbance interferes with PSE performance, perhaps schizophrenic patients of low intelligence describe less exact symptoms and more diffuse disturbance. Further study of the cohort over time might shed light on this association and point to links with the kind of deficit reported by Crow and colleagues.

British Journal of Psychiatry (1987) **150**, 340–344

The Scottish First Episode Schizophrenia Study

IV. Psychiatric and Social Impact on Relatives

THE SCOTTISH SCHIZOPHRENIA RESEARCH GROUP

An assessment of 31 main care-giving relatives living with schizophrenics was carried out using the General Health Questionnaire and the Social Adjustment Scale by Self Report.

More than 75% of relatives had a high probability of themselves being a psychiatric case. Relatives also showed social role dysfunction and impairment especially marked in social and leisure activities. Relatives' distress was related to the level of symptoms in patients, as assessed by the Present State Examination.

The effect the family has on the schizophrenic patient has been widely studied (e.g. Brown *et al*, 1972; Vaughan & Leff, 1976; Falloon *et al*, 1982). However, there are few reports which have assessed the impact of the illness on close family members living with schizophrenics. Early studies assessed mainly the impact on the family of new community-based programmes of management by comparing the burden on relatives of schizophrenics treated in the community with those whose illness had been managed in hospital (Grad & Sainsbury, 1963, 1968). Relatives did indeed have high burden scores. Hoenig & Hamilton (1966) followed a cohort of schizophrenics admitted to hospital and subsequently discharged; 42% of relatives reported disruption in family life. In these early studies no reliable information was provided on relatives' psychiatric functioning.

In a recent study (Gibbons *et al*, 1984) almost one-third of relatives of schizophrenics who used the services of a district general hospital psychiatric unit in Southampton scored in the 'caseness' range of the General Health Questionnaire (Goldberg, 1978; Goldberg & Hillier, 1979). This indicates that they had a high probability of being psychiatric cases. The latter study examined schizophrenics at varying stages in their illness. The present study aims to assess the impact of the patient's illness during the first schizophrenic episode and to identify patient characteristics associated with relatives' distress.

Method

Population

Relatives had to live with the patient and be a main care-giver. This was operationally defined as the spouse of a married patient, the parent of a single patient or failing this, an adult offspring. Thirty-nine patients lived with relatives of whom 31 were assessed—24 parents, five spouses and two adult offspring.

Assessment

Relatives were assessed by the General Health Questionnaire (GHQ-28) (Goldberg & Hillier, 1979) and the Social Adjustment Scale Self-Report (SAS-SR) (Weissman & Bothwell, 1976) during the first week of the patients' admission. The GHQ-28 assesses psychological distress; it provides a rating of severity and by means of a threshold score can divide a population into those with a high or low probability of being a psychiatric case (Goldberg, 1978). On the basis of Scottish studies (Hobbs *et al*, 1983; Livingston & Livingston, 1984) respondents who scored five or more were considered cases. The GHQ-28 has four subscales assessing somatic symptoms, anxiety/insomnia, social dysfunction and severe depression. The SAS-SR, a 54-item questionnaire completed by the relative, yields an overall adjustment score and a rating of seven role areas: work, social and leisure activities, functioning within the nuclear family, functioning within the extended family, and marital, parental and economic functioning. A higher score indicates poorer adjustment. Differences between groups were tested by independent *t*-tests; correlations between groups were measured by the product moment correlation coefficient.

Results

The mean score for relatives on the GHQ-28 was 10.81 (s.d. 7.61), well above the caseness threshold. Twenty-four relatives (77%) had scores above the threshold. The relatives' mean score was high on the anxiety/insomnia (9.45, s.d. 5.43), social dysfunction (9.45, s.d. 4.19) and somatic subscales (8.13, s.d. 5.10). GHQ total scores suggest a very high level of psychological distress, about three times the community norm (Goldberg *et al*, 1976; Finlay-Jones & Burvill, 1977).

Social adjustment scores for relatives when compared with the self-assessment of a normal community sample (Weissman *et al*, 1978) (Table I) were higher in all roles except marital and parental functioning. Relatives scored significantly worse on global adjustment ($t = 2.53$, $P < 0.02$) and social and leisure functioning ($t = 3.96$, $P < 0.01$) but better on parental functioning ($t = 3.62$, $P < 0.01$).

**$P<0.001$

1. Taken from Weismann *et al* (1978)

The population was next divided into cases (a score of 5 or more on the GHQ-28) and non-cases (a score of 4 or less). Differences in scores between the two groups were statistically significant on all GHQ subscales, cases performing less well (P values ranged from <0.002 to <0.0001); the greatest difference was in anxiety/insomnia ($t=5.22$, $P<0.0001$). Probable psychiatric cases had poorer social adjustment. Difference between the two groups were statistically significant in functioning in the nuclear family ($t=2.44$, $P<0.02$) and in work ($t=2.57$, $P<0.01$).

Relatives' psychological functioning was compared with patients' total scores and subscores on the Present State Examination (PSE) (Wing *et al*, 1974; Wing & Sturt, 1978). The subscores were for the following PSE syndromes: delusional and hallucinatory syndrome, behaviour, speech and other syndromes; specific neurotic syndromes, and non-specific neurotic syndromes. Statistically significant positive correlations were found between total PSE scores and both GHQ and social adjustment total scores ($r=+0.50$, $P<0.005$ and $r=+0.45$, $P<0.01$ respectively). Non-specific neurotic syndrome scores correlated significantly with GHQ total scores ($r=+0.40$, $P<0.03$), delusional and hallucinatory syndrome scores with social adjustment total scores ($r=+0.42$, $P<0.02$).

Relatives' psychosocial distress did not correlate significantly with patients' scores on Krawiecka and Wing Scales (Wing, 1961; Krawiecka *et al*, 1977) nor was it related to Research Diagnostic Criteria or Feighner categorisations (Feighner *et al*, 1972; Spitzer *et al*, 1978). A family history of psychiatric disorder was not associated with relatives' functioning nor was relationship to the patient.

Discussion

We believe this to be the first study to report the impact on relatives of a first episode of schizophrenia. The results demonstrate a very high incidence of psychological distress in relatives with anxiety-based symptoms the most prominent feature. The severity and frequency of such distress were far higher than in the Southampton study (Gibbons *et al*, 1984) but relatives were seen during a period of crisis, the first admission of the patient to a psychiatric hospital. In Southampton, patients had been ill longer; probably relatives had adapted over a longer period of time. Also, self-selection of relatives may indicate bias. For example, the most concerned relative may have visited the patient most frequently after admission and thus found himself identified as the main care-giver. Levels of disturbance in the present study were higher than in other groups of relatives. For example, 3 months after severe head injury 57% of relatives scored within the caseness range of the GHQ but only 10% of relatives of the mildly injured did so (Livingston *et al*, 1985*a*). Approximately 65% of supporters of the elderly mentally infirm had similar GHQ scores (Gilleard *et al*, 1984). The higher levels of disturbance in relatives in the present study may be partly explained by the time of assessment.

Social adjustment was also impaired with global adjustment and social and leisure functioning being significantly worse than in a community sample. Also, this group of relatives had poorer global social adjustment than the relatives of the severely head injured (Livingston *et al*, 1985*b*). However, relatives functioned better in their role as parents or marital partners than the comparison group. Perhaps this is because relatives saw themselves as striving hard in these roles.

Relatives who were cases, as defined by the GHQ-28, had higher scores on all GHQ subscales and performed less well at work and as part of the nuclear family. However, there were marked trends towards poorer functioning in all roles with the exception of economic functioning.

Relatives' distress was related to symptoms in patients as assessed by the PSE. The correlation between total PSE and total GHQ scores was accounted for mainly by neurotic symptoms in the patient; in contrast, correlation with social adjustment total scores was greater in those with florid psychotic symptoms. This might suggest that anxiety in the patient produces anxiety in the relative, whereas psychotic symptoms bring about an adjustment in the relatives' social life. A similar finding, namely that personal distress in relatives was associated with patients' emotional lability rather than active disturbed behaviour was found in demented day patients (Greene *et al*, 1982).

Psychiatric disorder is common in the community (Goldberg *et al*, 1976; Finlay-Jones and Burvill, 1977) but such disorders are usually brief and remit spontaneously. Planned follow-up of relatives in the present study will indicate whether the very high level of psychosocial distress in these patient supporters persists as it did with the relatives of head injured patients for at least 1 year (Livingston *et al*, 1985*b*). The evolution of social functioning is less well known but it is likely it will follow the course of the relatives' psychiatric functioning.

In conclusion, the results in the present study suggest involvement with families should start from the first admission of the patient to hospital, not only for the needs of the patient but also for those of relatives.

Acknowledgements

We wish to thank patients, relatives and nursing staff for their cooperation; Janssen Pharmaceutical and Lundbeck Limited for financial and other support; Mr C Selby, City Hospital, Nottingham, for prolactin estimations; and Mrs M. McCormick and Miss P. Cowan for secretarial assistance.

Five-year Outcome and Prognosis in Schizophrenia:

A Report from the London Field Research Centre of the International Pilot Study of Schizophrenia

R. PRUDO and H. MUNROE BLUM

A sample of 100 schizophrenic patients admitted to London area psychiatric hospitals were examined as part of the International Pilot Study of Schizophrenia. Clinical and social outcome were variable. At 5-year follow-up, 49% had good symptomatic outcome and 42%, good social outcome. Poor social functioning at inclusion was predictive of poor symptomatic outcome. Illness history (IH), occupational functioning (OF), social relationship functioning (SRF), negative and non-specific symptoms (NNS) at initial evaluation, and their interaction with sex and race accounted for 32% of the 5-year symptomatic outcome variance ($n=84$; $F=3.48$; $P<0.001$). OF, SRF, housing status, NNS and their interaction with sex, race and age accounted for 47% of the social outcome variance ($n=62$; $F=2.62$; $P<0.007$).

This paper examines the 5-year outcome and factors predictive of outcome in 100 schizophrenic patients admitted to London area psychiatric hospitals, reflecting data from the London Field Research Centre of the International Pilot Study of Schizophrenia (IPSS) located at the Medical Research Council (MRC) Social Psychiatric Unit, Institute of Psychiatry, Camberwell, London. The World Health Organisation (WHO) Collaborating Investigators at the London field research centre at inception included Dr J. K. Wing, Dr J. Birley and Dr J. P. Leff. The IPSS represents a WHO-sponsored transcultural psychiatric investigation of 1202 patients in nine countries—Columbia, Czechoslovakia, Denmark, India, Nigeria, Taiwan, the Soviet Union, the United States and the United Kingdom. The IPSS was carried out in three phases: the Preliminary Phase, the Initial Evaluation Plan and the Follow-up Phase. During the preliminary phase, administrative, operational and organisational procedures were established and tested. In the initial evaluation phase approximately 135 patients were selected and examined at each centre from among those patients contacting the centres during the 1-year period from 1 April 1968 to 1 April 1969. The follow-up phase had two major components. Two years following the initial evaluation of patients there was a follow-up evaluation, which was repeated 5 years after patients' inclusion in the study. This report is based on the initial evaluation and 5 year follow-up data. Because of limited resources, a comprehensive second year follow-up at the London centre was omitted.

The broad aims of WHO-sponsored IPSS were to tackle methodological problems relevant to a large scale international psychiatric study and to answer questions about the nature and distribution of schizophrenia. The basic questions were formulated as follows:

(a) In what sense can it be said that schizophrenic disorders exist in different parts of the world? Do they differ in form or content? Does the clinical course differ?
(b) Can other functional psychoses also be recognized and do they run a recognisably different course?
(c) Can techniques be developed for recording and classifying symptomatology reliably?
(d) Can teams of research workers be trained to use those techniques so that comparable observations can be made in both developed and developing countries?

It is beyond the scope of this paper to enlarge on these extensive goals except where relevant to 5 year outcome and prognosis. The reader is referred to Volume 1 of the Report of the IPSS (WHO, 1973) which gives a detailed account of the origins, objectives and design of this study, while the 2-year follow-up report (WHO, 1979) contains a comprehensive account of the overall results. The 5-year follow-up data will be presented in a future IPSS volume.

Although schizophrenia is perhaps generally regarded as an illness with poor outcome, a range of variability in outcome has long been recognized and many attempts have been made to identify various symptomatic, past history and sociodemographic factors that are highly correlated with good and bad outcome. The initial evaluation and the 5-year follow-up phases of the IPSS provide data which make it possible to consider the degree of variance in the outcome of schizophrenic patients that is explained by such predictors. An important advantage of the IPSS data over that used in many other studies of outcome and prognosis is that (a) it was collected in a prospective study; (b) both the initial evaluation and follow-up reassessment of psychopathology were carried out by well-trained investigators with the use of standardised research instruments; (c) the reliability of the clinical evaluation procedures was assessed both within and across research centres; and (d) the data relates to patients from nine different parts of the world, adding a cross-cultural dimension to the investigation of predictors. While the IPSS included for comparative purposes patients with diagnoses other than schizophrenia, this report is concerned with schizophrenic patients alone, since patients with other diagnoses in the UK sample form too small a group to analyse separately. Where results for outcome and factors predictive of outcome in the UK sample differ markedly from that of other IPSS centres, this will be indicated.

Most previous studies on prognosis have operated with unstandardised diagnostic concepts, and predictors and characteristics of outcome whose assessment is not directly replicable, making comparison of results from different studies difficult. Despite these difficulties it is possible to find broad areas of agreement between different studies and to derive hypotheses which could be tested on data from the 5-year follow-up phase of the IPSS London centre. Previous studies have suggested many predictors of outcome drawn from sociodemographic, past history, personality and psychopathology variables.

Many investigators have emphasised the roles of community acceptance, living arrangements, social relationships, and occupational and economic status in influencing how well a person with schizophrenia will do over time (Pasamanick *et al*, 1967; Fairweather *et al*, 1969; Stein *et al*, 1975; Lamb, 1978; Wallace, 1980). In general, findings have indicated that variables predict their like outcome functions. For example, Strauss & Carpenter (1974, 1977) in their analysis of the IPSS follow-up data from the Washington Centre found that employment status and quality of social relationships at inclusion were most predictive of 2 and 5-year follow-up occupational status and social relationships, respectively. This reflects the overall IPSS 2-year follow-up results demonstrating a role for social isolation and marital status in predicting outcome. Illness history has been identified as an important predictor of outcome in schizophrenia by a number of authors (Langfeldt, 1956; Vaillant, 1964). While there has been controversy over the predictive usefulness of subclasses of schizophrenia and presenting psychopathology (Langfeldt, 1956; Strauss & Carpenter, 1974; Hawk *et al*, 1975), there exists some evidence that 'positive' symptoms predict a good response to neuroleptic drugs, while the presence of 'negative' symptoms bodes poorly for long-term outcome irrespective of drug treatment (Mackay, 1980). Positive symptoms included: 'delusions present much of time', 'presence of delusions of grandeur', 'presence of hallucinations', 'hears thoughts aloud'. Negative and non-specific symptoms included: 'uninformed', 'recent change in concentration', 'restricted affect', 'poor rapport with interviewer', 'recent change in interests', 'poor insight'. Extrapolating from these findings one might expect that for a schizophrenic population receiving standard treatment procedures (including neuroleptic drugs), 'positive' symptoms would not be predictive of poor outcome while 'negative' symptoms might be. The results of the 2-year follow-up data from the IPSS, also suggests that negative and non-specific symptoms present at the time of inclusion were predictive of poor outcome (WHO, 1979).

Many prognosis studies tend to ignore evaluation of the interrelationships of multiple predictor variables and their combined influence on outcome. The assessment of potential confounders and interaction factors is often ignored. Investigation of the interrelationships of preselected independent variables and their cumulative effect on outcome with consideration given to potential confounders and interaction terms is indicated as evidenced in the IPSS 2-year follow-up results (WHO, 1979). The hypotheses addressed here include both those in which like inclusion variables were expected to predict like 5-year follow-up functions and those in which specific inclusion variables were expected to predict unlike 5-year follow-up functions. The questions addressed were: (1) What social, illness history and symptom factors will be related to or predictive of symptomatic outcome? (2) What social, illness history and symptom factors will be related to or predictive of social outcome? (3) What are the interrelationships of these predictor and outcome variables? It was hypothesised that poor inclusion social functioning, poor inclusion illness history and the presence of negative symptoms at inclusion would each be positively associated with poor symptomatic and social outcomes at 5-year follow-up. It was further hypothesised that inclusion 'positive' symptoms would not be associated with poor clinical and/or social outcomes at 5-year follow-up.

Method

Patient selection

This report is based on a prospective study of 100 schizophrenic patients examined at the London Field Research Centre. The initial patient sample was obtained by screening the case notes of all subjects with functional psychoses admitted to the Bethlem Royal and Maudsley Hospitals and to Cane Hill Hospital during the study period. The patients selected for the study were between the ages of 15 and 44 years. Exclusion criteria were chosen to screen out chronic patients and those who illness may have been caused or significantly influenced by an organic condition. Chronic patients were defined as those having total periods in hospital of 2 years or more in the previous 5 years, including re-admission, or severe psychotic symptoms in the episode of inclusion, probably continously present for more than 3 years.

Inclusion criteria

Inclusion criteria consisted of symptoms, such as hallucinations, whose presence automatically qualified the patient for inclusion regardless of the degree of symptomatology, and those, such as disorders of form of thinking, considered as a basis for inclusion only if present in severe degree. About one-third of the patients were local residents of Camberwell, a completely urban area, mostly inhabited by working class people but with a sizeable middle class population, while the majority of the remaining patients came from nearby districts. Patients were informed as to the nature of the study and participated voluntarily.

Rating schedules

Patients identified as being potentially suitable for inclusion were interviewed by experienced psychiatrists using a number of standardised ratings instruments. These included a semi-structured sign and symptom interview of established reliability, the 'Present State Examination' (PSE) (Wing *et al*, 1974) and a 'Psychiatric History (PH) and Social Description Schedule' (SD). The individual ratings on the PSE can be grouped to produce 35 syndrome scores. A computer program, CATEGO, has been developed to process the syndrome scores and leads to standardised clinical groupings. Additional information concerning the psychiatric history can also be expressed in a standard form and processed by CATEGO so that it contributes to a final diagnostic category (Wing *et al*, 1974). The PH and SD Schedules contain nine sections of psychiatric history items and twelve sections of social description items. The reliability of the PH and SD Schedules was less extensively documented than the PSE. Four main types of schedules were used at the 5-year follow-up point: the PSE, the Follow-Psychiatric History Schedule (FUPH), the Follow-up Social Description Schedule (FUSD) and the Follow-up Diagnostic Assessment Schedule (FUDA). The main purpose of the FUPH was to describe the course of the patient's illness in the interval between initial evaluation and the 5-year follow-up, while the main aim of the PUSD was to provide an account of the socioeconomic changes occurring to the patient since the initial evaluation. Areas covered included quality of housing, quality and type of work, education and social activities. The FUDA Schedule required the psychiatrist to make an overall diagnosis of the patient at the time of follow-up and to describe the findings. As well as interviews with the patient, information was obtained from family members, health records and health professionals. Following the initial screening assessment, suitable patients were given a clinical diagnosis by the interviewing psychiatrist based on all the available information at the initial evaluation and using the description and categories provided by the 'International Classification of Diseases—Eighth Revision (ICD-8)' (WHO, 1965). Of the 100 patients given a clinical diagnosis of schizophrenia at inclusion, 77% of the diagnoses were paranoid schizophrenia, 10% were hebephrenic schizophrenia, and 8% were schizo-affective. Using the CATEGO program, 79% of the patients given a clinical diagnosis of schizophrenia fell into the important 'Class S'. This class contains patients with at least one of Schneider's first-rank symptoms, most of which are considered to be highly discriminating for a diagnosis of schizophrenia. Follow-up interviews were conducted 5 years after admission to the study by one of the authors (RP). At this time the four follow-up schedules were administered.

Outcome criteria

The criteria used to assess outcome in schizophrenia have varied widely from study to study. Some investigators report 'global' assessments, while others stress either symptomatic improvement or social outcome. Recent studies have emphasized the need to view outcome as a multidimensional construct. Brown *et al* (1966), for example, pointed out that improvement within one individual area of functioning does not necessarily correlate with improvement in other areas; patients with, for example, extensive delusions may be able to work. In our paper both symptomatic and social outcome scales have been utilised as measures of outcome.

The symptomatic measures of outcome are based on the type, severity and duration of symptoms during the 5-year follow-up period. Four symptomatic outcome categories have been created, based on the total time patients experienced either florid episodes of major mental disorder or marked residual symptoms or defect state, warranting an ICD diagnostic label over the 5 years (Table I). Only disorders subsumed under the category 'Psychosis' (ICD-8) were included as major mental disorders. Mental disorders subsumed under the 'Neurosis' category and minor or occasional residual symptoms, such as delusional fragments or hallucinations, have not been taken into account in this outcome measure, with the exception of the best outcome category (Table I). While a variety of overall symptomatic outcome scales have been utilised in previous research, including length of hospitalisation during the follow-up period or symptom profiles in the month prior to follow-up, this new scale was preferred because it seemed to reflect a more complete picture of the symptomatic course during the 5-year follow-up period and more fully utilised the comprehensive information available to this study.

Social outcome categories have been created based on the assessment of three distinct areas utilising the IPSS social schedules: occupational functioning, social functioning and housing status in the year prior to follow-up. Eleven specific social outcome variables subsumed under these three categories were utilised and score 0 for good functioning and 1 or more for poor functioning, and these items summed to create major variables, such that a low score reflects good functioning and a high score poor functioning (Appendix I).

Patients

At the time of inclusion into this study the patients were predominantly male (64%), young (71% in the age range 15–34 years), and unmarried (81%). Thirty-four percent had no psychiatric history prior to their inclusion in this study, whilst about half (53%) of the remaining 66 patients had a psychiatric history of less than 1 year. Thus, the majority of the patients (70%) had either no prior psychiatric history or a history of less than 1 year.

Nineteen percent of the patient population was non-white (12% of West Indian origin and 7% other), the great majority of whom were born overseas. Comparison of white and non-white subjects by age, sex and marital status revealed no significant differences. The proportion of the Camberwell population made up of West Indian immigrants (the only group large enough to justify a separate analysis in this study) was estimated in a full census in 1971 to be 4.9% while a 10% census in 1966 indicated 4.7% (Leff *et al*, 1976). It would appear that West Indian patients were over-represented in this UK sample (12% *vs* 4.9%). This is what Leff and his colleagues found when screening all psychiatric admissions in Camberwell as part of an epidemiological study of mania (Leff *et al*, 1976). Whilst there are a number of possible explanations for this over-representation, many studies have reported higher rates of psychiatric morbidity among immigrants than non-immigrants, including West Indian immigrants (Hemsi, 1967). In the 25–44 age-group, Rwegellera (1977) has calculated that the inception rates for schizophrenia are significantly increased among West Indian Camberwell residents as compared with Camberwell United Kingdom residents (0.80 vs 0.17—inception rate per thousand of the population at risk per annum). The findings of our study, as described later, indicate non-white race to be associated with poor prognosis and outcome.

Follow-up

At the 5-year follow-up, strenuous efforts were made to locate and interview each of the 100 schizophrenic patients. Apart from those who were in hospital (13%), patients were usually interviewed at home. It was possible to fully interview and evaluate 65 subjects after 5 years. This evaluation included a patient interview, where possible an additional interview with a relative, a computer search of the Department of Health and Social Security 'Mental Health Enquiry Record', which provided details of all UK hospital admissions during the follow-up period, and extensive perusal of all relevant hospital and other records. These 65 patients are included in all the analyses.

Comprehensive clinical information (other than personal interview) was available for a further 23 patients, using the same data gathering strategy. Most of these 23 patients had moved out of the country or well away from London, and it proved impractical to interview them. This group included six patients who had died during the follow-up period, five by suicide. Since these patients could be classified with regard to overall clinical outcome they have been included along with the 65 fully evaluated subjects in some analyses relating to clinical outcome. However, they have been omitted from analyses of social outcome as this information was incomplete. Twelve further patients were regarded as having limited follow-up information and these have been omitted altogether from any analyses.

A number of variables were considered to determine whether the non-interviewed patients were representative of the entire cohort. The non-interviewed group ($n=35$) were more frequently non-white than the interviewed ($P=0.001$). Moreover, of the 23 patients who could be classified with regard to clinical outcome but had not been interviewed at follow-up, 74% had a poor clinical outcome compared with 40% of the interviewed subjects ($P=0.03$). There was no difference by age, sex, marital status, or diagnosis at inclusion. Of the 35 non-interviewed subjects, 14 had moved to other countries (10 had returned to their country of origin), six had moved to distant parts of Britain, four lived a vagrant life style, five patients could not be located at all and one person refused to be interviewed. Six remaining patients were deceased. The excess of non-white patients who were in the 'not fully interviewed' category appears to be explained mainly by the repatriation of those patients with chronic schizophrenia to their countries of origin (to their families and extended families). Repatriation may also account for the excess of patients with poor clinical outcome found in the 'not fully interviewed group'.

Because of the large amount of information collected on each subject (for example, there are 360 items in the PSE alone), it was necessary to reduce and group the data. Items of information were grouped using a combination of statistical procedures and clinical judgement. In this study, it was anticipated that while particular configurations of variables would not always demonstrate strong intra-group statistical cohesion, these items would be meaningfully grouped in terms of their additive influence on outcome. Several constructs were selected as representing the prediction and outcome pictures of interest. These were: illness history (mental illness in family, history of physical illness in subject, obvious precipitating event, prior psychiatric history and episode preceded by lengthy symptoms), social functioning and 'negative' and 'positive' symptoms as predictors, and clinical and social functioning as outcomes. Social functioning was made up of occupational, social relationship and housing variables. For example, the inclusion occupational factors involved, 'number of job changes in the past year', 'financial dependence on family', 'ever had a full time job', 'had job in year prior to inclusion'. The inclusion social relationship factor involved, 'social isolation', 'marital status', 'lives alone', 'sees friends on a regular basis', 'sees relatives on a regular basis'. Inclusion housing status included, 'number of moves compared with culture', 'number of moves in past year', 'number of rooms available for personal use', 'length of time at current address' and 'home ownership'. Thus, the major predictor and outcome variables were created by summing the sets of items reflecting each major construct. The major predictor variables were created to reflect mutually exclusive constructs, as were the major outcome variables.

Correlation and multiple regression analyses comprised the primary analytic approaches to the examination of the study hypotheses. Correlation analyses were used to examine the associations between variables of interest, whilst multiple regression analyses were utilised in assessing the predictive value of specific variables while controlling for the potential confounding or interaction influences of age, race and sex.

Results

Symptomatic outcome

Eighty-eight schizophrenic patients could be classified across the four symptomatic outcome categories. Details are given in Table I.

Nineteen percent of the patients were in the best outcome category. These patients experienced no further episodes of major mental illness following the episode of inclusion nor any residual psychotic symptoms. The mean time spent in the episode of inclusion for these patients was 22 weeks. A further 30% of the patients were in the next best group having had further episodes of major mental disorder though, in total, for less than one year of the 5-year follow-up period. Half the patients, then, could be said to have had a good symptomatic outcome. Of the remainder, the great majority had experienced major mental disorder for at least half the 5-year follow-up period (including 10% who had never recovered symptomatically from the episode of inclusion).

TABLE I

Percentage distribution of subjects by symptomatic outcome at 5 years

	Good outcome		*Bad outcome*	
Number of patients	*1*	*2*	*3*	*4*
88	19%	30%	10%	41%

Outcome categories: (1) No further episodes of major mental disorders following episode of inclusion. No residual psychotic symptoms. Mean time spent in episode of inclusion was 22 weeks. (2) Further episodes of major mental disorder in addition to episode of inclusion. Total time in episodes less than 1 year. This category includes three subjects who did not have further episodes of major mental disorder but did have psychotic residual symptoms and have therefore been excluded from Group 1. (3) Between 1 and 2½ years spent in episodes of major mental disorder. (4) More than 2½ years in episodes of major mental disorder (including six subjects deceased at follow-up).

The 17 patients in the best outcome category (Group 1) were compared to the remaining 71 patients along a variety of parameters. Whilst these 17 patients were slightly younger than the other patients (78% *vs* 67% aged 15–34 years), they did not differ significantly on comparisons of sex, marital status, prior psychiatric history or level of social functioning at inclusion. Similarly, the 36 patients in the worst outcome category (Group 4) were compared to the remaining patients. Sex and inclusion social functioning were significantly associated with poor outcome ($P = 0.025$ in both cases). Males and those with poor inclusion social functioning were more likely to fall into the worst outcome group.

In order to control for the possible role of previous psychiatric history on overall symptomatic outcome, 20 of the 65 fully assessed patients who had no prior history at inclusion were compared in terms of symptomatic outcome with those who did. Fifty-three per cent of those with no prior psychiatric history had a poor symptomatic outcome compared with 45% of those who did ($P = \text{NS}$). This surprising result may reflect the fact that chronic patients were excluded from the study so that most of the patients with a prior illness had a history of less than one year and had been in hospital for less than 6 months in the preceding 5 years. In other words, those patients with a psychiatric history prior to inclusion in this study had psychiatric disorders of relatively recent origin with short hospitalisations, thus tending to minimise clinical differences between the two groups. In addition, psychiatric 'illness history' refers only to the presence or absence of prior episodes and does not include other important illness history characteristics such as length of the psychotic episode, premorbid personality or family history of mental illness. This broader concept of illness history is examined later in the paper in the section dealing with prognosis.

In addition to the data contained in Table I, information was collected to provide diagnostic details of the various episodes of psychiatric disorder which contributed to the overall symptomatic outcome result. The 65 fully assessed schizophrenic patients between them experienced 115 episodes of major mental disorder during the 5-year period; 84% of these episodes were schizophrenic psychoses (ICD 295) and 16%, affective psychoses (ICD 296). In other words, one in six episodes experienced by patients with an established schizophrenic disorder were of a pure affective type. The episodes of schizophrenic psychoses were predominantly of the paranoid type (295.3) with a small number of schizo-affective (295.7) and hebephrenic types (295.1). At 5-year follow-up, of the 65 patients for whom we had a PSE, 29% had delusions or hallucinations in the month prior to interview, 32% had behavioural disturbances which were probably related to their schizophrenic illness, 48% had "neurotic" symptoms and 32% were asymptomatic.

Social outcome

Two overall social outcome categories were created on the basis of total scores taking into account functioning in social relationships, housing status and occupational performance in the year prior to interview. Of the 65 fully interviewed patients who could be classified with respect to social outcome, approximately two-thirds (42/65) were categorised as having no severe impairment at 5-year follow-up as determined by a total social functioning score of 0–3, and one-third as showing evidence of severe social impairment with social functioning scores ranging from 4–7 (Table II). None of the patients in the 0–3 or 'no severe impairment' group had a score of 3 in any one of three social outcome areas, i.e. there was no major deficit in any one area. The mean score was 1.5. Twenty-five of the 42 patients in this social outcome group had handicap scores of only 0 or 1. Social outcome was not significantly associated with age or marital status.

TABLE II

Percentage distribution of subjects' outcome social functioning scores[1]

Score	*No severe impairment*[1] *0–3*	*Severe impairment*[2] *4–7*	*8–11*	*Total*
n	42	22	1	65
%	66	33	1	100

1. Social functioning scores were based on assessment of occupational performance, social functioning and housing status.
2. Severe social impairment defined as social functioning scores ranging from 4–11. A patient with a score in this range would have a deficit in each of the areas of assessment or would have a major deficit in at least one of these areas. None of the patients in the 0–3 group had a score of 3 in any one of the three social outcome areas.

Of these 65 patients, 40% (26) worked a full 12 months during the final year of the 5-year follow-up and another 12% (8) worked more than 6 months of the final year. At follow-up 74% (48) were socially active within their households to the extent expected of a person without a psychiatric disorder and 43% (28) socialised outside of the household and were involved with community activities at this same level of expectation, while only 35% (23) experienced satisfactory sexual functioning. Sixty-nine per cent of these patients (45) lived in housing conditions equal to or better than the norm for British culture.

Combined social and clinical outcome

Clinical and social outcome were significantly correlated ($P=0.0001$). Forty-nine per cent of the 65 patients with complete social and clinical outcome information had good outcomes in both areas of functioning (i.e. category 1 or 2 on symptomatic outcome (Table I) and a score of 0–3 on social functioning (Table II). It should be remembered, however, that the good symptomatic outcome group included some patients with disorders subsumed under ICD-8 'Neurosis' category as well as some patients with mild schizophrenic residual symptoms. The good social outcome category also included patients with some deficits, though none were severe. For example, a housewife with children at home (social functioning score = 1, gained in the occupational area) was unable to manage all the housework in the way she had prior to her illness because she felt 'slowed up' and could not 'do things as fast as I could before'. Her relatives helped out with the household duties, and with this support her household ran well. Another patient (social functioning score = 2, gained in social relationships) had an excellent work record as a schoolteacher and supported himself in independent lodgings. However, he was unable to establish and maintain peer or heterosexual relationships. Another patient (social functioning score = 2, gained in occupational functioning) lived in a youth hostel, was socialising well both in his household and in the community but had been employed in a menial job well below his level of education since his illness. These examples are intended to give both a flavour of the extent of the social handicaps included in the 'good' social outcome group and also to illustrate how relatively focused some of the social handicaps may be in the wake of schizophrenic illness.

Twelve per cent of the patients were found to have a good social outcome but a bad symptomatic outcome while 6% had a good symptomatic outcome, but a bad social outcome.

Prediction of symptomatic outcome

A majority of the hypotheses concerned with symptomatic outcome were confirmed. Specific illness history factors at inclusion into the study (particularly 'no precipitating event' and 'lengthy symptoms') were positively and significantly associated with poor symptomatic outcome at 5-year follow-up. Somewhat unexpectedly, poor social functioning at inclusion was also positively and significantly associated with poor symptomatic outcome. Positive symptoms did not demonstrate any relationship of significance with poor symptomatic outcome. Negative and non-specific symptoms did not demonstrate any significant relationship with

TABLE III

Predictor variables which correlate significantly with symptomatic outcome*

Predictor variable	*Clinical outcome*	*n*
	Pearson's R	
1. Illness history	0.22	84
2. Total social functioning	0.29	88
Occupational functioning	0.28	88
Social relationship functioning	0.21	88
Housing status	N.S.	88
3. Sex	0.22	88
4. Race	0.23	88

*Significant at $P<0.05$ level.

symptomatic outcome and therefore did not support the related hypothesis. Male gender was positively and significantly correlated with poor clinical outcome, as was non-white racial status, though age did not demonstrate a significant relationship with symptomatic outcome. Table III gives details.

Subclasses of the variable categories were introduced in a stepwise regression analysis, a procedure that sequentially adds predictor variables in order of their contribution to outcome, combining them to increase the overall correlation with outcome. Inclusion illness history, occupational functioning, social relationship functioning and negative and non-specific symptoms were the only variables which entered the model at an acceptable level of significance; these accounted for 23% of the variance in symptomatic outcome. When first order interaction terms were added to this model, three interaction terms met the significance criteria for acceptance. These interaction terms were such that non-white subjects with poor inclusion illness history has poorer symptomatic outcome than white subjects with poor inclusion illness history; male subjects with inclusion positive symptoms had poorer symptomatic outcome than females with inclusion positive symptoms; and, non-white subjects with poor inclusion social functioning had poorer symptomatic outcome than white subjects with poor inclusion social functioning. This full model including interaction terms explains 32% of the variance in symptomatic outcome. Given that interaction is present, the assessment of confounders is questionable. When interaction terms are excluded from the model however, sex and race enter in a significant fashion.

These results support the hypotheses identifying inclusion illness history, social functioning and negative and non-specific symptoms as predictors of symptomatic outcome and underscore the usefulness of including interaction terms in the analyses. Table IV summarises the significant findings of the symptomatic outcome regression analyses.

TABLE IV

Multiple regression analyses with symptomatic outcome as dependent variable (n = 84)

Dependent variable:

Clinical outcome

Independent variables:

i) Illness history
ii) Occupational functioning
iii) Social relationship functioning
iv) Negative and non-specific symptoms
—Variance in outcome accounted for: 23%
—F of this equation: 5.69 ($P < 0.0005$)

Interaction term added:

v) Race × illness history
vi) Sex × positive symptoms
vii) Race × social functioning
—Variance in outcome accounted for: 32%
—F of this equation: 3.48 ($P < 0.001$)

Prediction of social outcome

While certain inclusion psychopathological items were predictive of symptomatic outcome they were not predictive of social outcome. Inclusion social factors were however, predictive of social outcome. Poor social functioning at inclusion was positively and significantly associated with poor social outcome at 5-year follow-up. Male gender was positively and significantly correlated with poor social outcome, as was non-white racial status. Inclusion illness history, negative and non-specific symptoms, positive symptoms and age were not significantly associated with social outcome. Table V further describes the inclusion variables which were significantly correlated with social outcome.

TABLE V

Predictor variables which correlate significantly with social outcome (n = 64)*

Predictor variable	*Pearson's R*
1. Total social functioning	0.44
Occupational functioning	0.23
Social relationship functioning	0.38
Housing status	0.28
2. Sex	0.24
3. Race	0.36

*Significant at $P < 0.05$ level.

Subclasses of the variable categories were introduced in a stepwise regression analysis. Inclusion occupational functioning, social relationship functioning, accommodation status and negative and non-specific symptoms accounted for 21% of the variance in social outcome. When first order interaction terms were added to this model, four interaction terms met the significance criteria for acceptance into the model. Thus, being older and having positive symptoms at inclusion or, being older and having a poor illness history at inclusion led to poorer social outcome. Further, being male and having a poor illness history at inclusion or being non-white and having a poor illness history at inclusion also led to poorer social outcome. This full model including interaction terms explains 47% of the variance in social outcome. Again, given that interaction is present the assessment of confounders is questionable. When the interaction terms are excluded from the model however, sex, and race enter at acceptable significance levels.

These results do not support the hypotheses which predicted significant relationships between inclusion illness history and social outcome and inclusion negative and non-specific symptoms and social outcome. The hypothesis concerning a relationship between inclusion social functioning and social functioning at 5-year follow-up was, however, supported. Social factors appear to be the best predictors of social functioning with illness history explaining only a very small part (2%) of the variance in social outcome. These results support the inclusion of interaction terms in the analysis. Table VI summarizes the significant findings of the social outcome regression analysis.

TABLE VI
Multiple regression analyses with social outcome as dependent variable (n = 62)

vi) Age × illness history
vii) Race × illness history
viii) Sex × illness history
—Variance in outcome accounted for: 47%
—F of this equation: 2.62 ($P < 0.007$)

Discussion

A striking finding is the variability in outcome for this group of stringently diagnosed schizophrenic patients. About one-fifth did not experience any further episodes of major mental disorder after the episode of inclusion while, at the other extreme, one-tenth never recovered from their episode of inclusion; more than one-third of the patients spent over half the follow-up period in episodes of major mental disorder. In the month prior to follow-up about one-third experienced delusions or hallucinations, one-third behavioural disturbances and one-third were asymptomatic. Overall, about half the patients could be considered to have both good symptomatic and social outcomes, even though our findings are biased in the direction of poor outcome because of an excess of non-white patients who appear to have a more unfavourable course. It should be noted that even among those considered to have a good outcome many patients, as we have documented, continue to experience some degree of symptomatic or social handicap. The London data suggest that schizophrenic patients who are initially relatively clinically homogenous and who correspond to the strict notion of schizophrenia assumed in the CATEGO Program have a wide variety of outcomes in the 5-year follow-up period. This finding is not necessarily due to variations in diagnostic criteria or other methodological difficulties. The variability in outcome evident at the London centre was one of the major findings in the IPSS and 2-year follow-up study as a whole. Moreover, there also appear to be clear differences in the course and outcome of different centres, with patients in centres in developing countries having a better course and outcome than those in centres in developed countries, suggesting that the course and outcome of schizophrenia is affected by sociocultural conditions (WHO, 1979).

With respect to prediction, our results identify specific illness history factors (especially 'no precipitating event' and 'lengthy history') as predictors of symptomatic outcome. However, the major prediction results described here suggest an important role for occupational and social factors in predicting symptomatic as well as social outcome. These findings reflect results of the IPSS 2-year follow-up generally, which found positive correlations between social isolation and marital status and all outcome measures. Strauss & Carpenter (1974), in a correlational analysis of the Washington IPSS 2-year follow-up data, reported positive correlations between social relations' and 'employment' with symptomatic outcome ($r = 0.28$ and $r = 0.28$ respectively, $P < 0.01$). These results are very similar to those reported here ($r = 0.21$ and $r = 0.28$ respectively, $P < 0.06$). Their 5-year follow-up results (Strauss & Carpenter, 1977) confirmed the importance of these predictors and showed that adding 'previous hospitalisations' to 'previous social contact' and 'previous employement' provided the most efficient way of anticipating 5-year outcome. In these results from the London centre, the relationships between inclusion illness history and symptomatic outcome and between inclusion social functioning and symptomatic and social outcome were demonstrated in correlational analyses. They persisted in multiple regression analyses controlling for the impact of age, race and sex. Reflecting the IPSS 2-year follow-up findings, social variables and illness history variables are about equal with respect to their ability to predict symptomatic outcome (WHO, 1979). (Unlike the 2-year follow-up results, symptomatic variables contribute somewhat less to prediction of outcome.) The variables examined in this UK study accounted for only 32% of the variance in the symptomatic outcome of schizophrenia and 47% of the variance in social outcome. This underscores the conclusion of other prognostic studies that no single predictor variable and no combination of key predictor variables is capable of explaining a majority of the variance in the outcome of schizophrenia, though utilising combinations of predictor variables clearly leads to a more complete picture of the prediction process. Nevertheless, the majority of the variance in outcome prediction remains unexplained. This may be because of methodological issues to do with this study or because certain recognised (as well as yet unrecognised) variables that have a bearing on the outcome of schizophrenia have been omitted. No attempt was made to control for treatment in this study nor to take into account such diverse factors as the quality of the home environment of patients (Brown *et al*, 1962), the impact of intervening life events (Leff & Vaughn, 1980), or the role of organic dysfunction (Kolakowska *et al*, 1985). Future research which addresses such additional intervening variables may bring new insights into the prediction of outcome in schizophrenia.

In conclusion the main results of interest in this study include the variability in clinical outcome and the finding that poor social functioning at inclusion is predictive of poor symptomatic outcome at 5-year follow-up. Thirty-two percent of the variance in symptomatic outcome was explained and to a great extent by social factors. There are a number of possible explanations for this finding. Poor premorbid social functioning may itself represent 'negative' type symptoms of schizophrenia, these symptoms tending to be associated with chronicity, though in this study 'negative' symptoms were not found to be positively associated with outcome. Poor social adjustment may also be seen to augur poorly for the patient's management of subsequent schizophrenic illness in general. Another possibility is that the social deficit identified at inclusion in this study as predicting subsequent poor symptomatic outcome is interacting with other established risk factors for schizophrenia thus giving rise to chronicity. For example, poor social functioning, e.g. work impairment in the patient, is known to engender the formation of critical, hostile and over-involved attitudes and behaviours by relatives towards the patient (Vaughn & Leff, 1981) and this to deleteriously affect the subsequent course of the schizophrenic illness (Vaughn & Leff, 1976). In support of this notion Vaughn and Leff reported that two-thirds of the patients with work impairment were found in those homes characterised by critical or over-involved relatives, and that furthermore 55% of the work-impaired patients from these homes relapsed in the subsequent 9 months compared with none from other homes. In other words, poor social functioning in the setting of schizophrenia may gain its status as a predictor of outcome by way of its interaction with the patient's family members. A variety of social factors such as inadequate housing or social isolation may also serve as chronic life stressors playing a role similar to that of life events in provoking further episodes of schizophrenia (Brown & Birley, 1968) while lack of social activities outside the home and social isolation may increase patient contact with critical or over-involved relatives to a degree which may be harmful (Brown *et al*, 1972). The overall results need to be interpreted with caution since no special attempts were made at inclusion to ensure a representative group of patients. The finding that social factors predict symptomatic outcome in schizophrenia may suggest emphasising particular therapeutic strategies since it has been demonstrated that maladaptive social functioning is amenable to change (Leff *et al*, 1982; Stein *et al*, 1975; Lamb, 1978; Wallace, 1980).

Appendix 1
Social outcome variables

Variables	*Possible range scores*[1]
1. Total Occupational Functioning	0–3
a) Months worked in past year	0–1
b) Occupation consistent with education	0–1
c) Occupational status compared with culture	0–1
2. Total Social Relationship Functioning	0–5
a) Active community involvement	0–1
b) Satisfactory sexual functioning	0–1
c) Socialises in community as normal	0–1
d) Socialises in household as normal	0–1
e) Currently socialises as did prior to onset of illness	0–1
3. Total Housing/Accommodation Status	0–3
a) Overcrowded	0–1
b) Unsatisfactory in other ways	0–1
c) Compared with culture	0–1

Clomipramine and 'Drive' in People with Anorexia Nervosa:
An In-patient Study

A. H. CRISP, J. H. LACEY and M. CRUTCHFIELD

Drugs can sometimes be helpful within the overall treatment and management of anorexia nervosa. In this study we have examined the impact of clomipramine on food and activity in anorectics engaged in a treatment programme enabling them to regain normal body weight. Consumption of the drug was associated with increased appetite, hunger and calorie consumption during the early stages of treatment. There was no impact on ultimate outcome. In this study it was evident that the drug was unnecessary for weight gain, but it may be helpful in other programmes, both short and long term, where the patient has sufficient trust (to tolerate the enhanced hunger experience) but is not involved in the same behavioural constraints. However, its possible value in such programmes has not been proven here. Meanwhile, we take our findings as further evidence that clomipramine increases drive behaviour and appetite in humans and may be beneficial in the treatment of affective disorders because of this effect.

It has been argued elsewhere (Crisp, 1967; 1978; 1984) that the best treatment for anorexia nervosa is a controlled intake of normal amounts of carbohydrate and calories in general; moreover, that drugs aimed at facilitating appetite can be counterproductive. Phenothaizines can sometimes be helpful through their tranquillising and immobilising effects but such consequences may induce a further reactive panic or hostility in anorectics who then feel trapped. Minor tranquillisers can occasionally be helpful, but also invite self-poisoning behaviour. The potential sedative effect of amitriptyline may be nullified by its occasional extreme carbohydrate-craving potential (Paykel, 1977), so alarming for the anorectic. Other hypnotics should be avoided at all costs. Otherwise they tend to become used by the anorectic in the same way that she sometimes abuses alcohol.

In 1977 we decided to study the impact of clomipramine on patients within our established in-patient treatment programme (Crisp, 1980*b*). It had been claimed that clomipramine, a tricyclic with some resemblance also to chlorpromazine, was potentially useful in the treatment of severe obsessional and phobic disorders. To the extent that there may be primary phobic and secondary avoidance behaviour and obsessional features within anorexia nervosa, it seemed justified to explore the effects of the drug within the syndrome.

Method

Patients are admitted to the anorectic unit at Atkinson Morley's Hospital after having committed themselves to treatment involving restoration of body weight to matched population mean levels consistent with the anorectic's age at onset of the condition (Crisp, 1980*a*). Patients eat 3000 calories prescribed per day within a normal diet and meal pattern. This generates a weekly weight gain of about 1.3 kg. At the time of the study (1977–1978) patients in the programme remained in bed without exception until they had reached 'target weight'. Patients are weighed routinely twice weekly. This behavioural programme is complemented by intensive individual and family psychotherapy involving the skills of a multidisciplinary team. Otherwise, of course, patients would not stay in it. On achieving target weight patients become progressively more mobile in a planned way with a view to discharge within a further 6 weeks. Out-patient follow-up involves monitoring of body weight and related behaviour, coupled with continuing psychotherapy.

For the purposes of the present study 16 female patients, successive admissions to the unit, all of whom understood the nature of the study and had given their informed consent in respect of involvement in it, were randomly allocated to consumption of 50 mg clomipramine or else placebo identical in appearance at 20 h each day.

Patients were also required to complete a series of analogue scales four times a day: before breakfast, before lunch, before dinner and just before retiring. These scales measured aspects of mood and appetitive behaviour, monitoring the daily fluctuations of hunger, appetite, anxiety, anger, sadness, tension, excitement, irritability and restlessness.

On one day each week the patients dispensed with the prescribed diet of the refeeding programme and chose whatever diet they wished. The food taken on this 'free day' was quantified. In addition, dietary histories were completed by the patients on other days of the refeeding programme selected at random. This allowed the dietary intake on the unsupervised 'free day' to be compared with the usual prescribed diet.

Overactivity is a common feature of anorexia nervosa. Any effect of the drug on activity would affect energy balance and hence weight gain. Therefore each week throughout the study, each patient spent 24 hours on a bed which was specially constructed to record and quantify movement (Crisp *et al*, 1970).

Results

The two groups—formed by random allocation of consecutive admissions—were well matched for mean duration of illness [clomipramine group 5 years (range 2-10 years), placebo group 3.7 years (range 1-7 years)] and mean age at onset [clomipramine group 15.9 years (range 13-20 years), placebo group 17.7 years (range 14–22 years)]. As populations they were mildly obese before the onset of illness and the social classes were represented equally in the two groups. At the time of admission the mean age of the clomipramine group was 20.9 years and that of the placebo group 21.4 years. One subject from each group presented with persistent vomiting and prolonged bulimia, whilst the other seven had lost weight and maintained low weight by abstaining from food.

Three patients in our sample, two of whom were found subsequently to be taking active substances, asked to leave the project before reaching their target weights. One, on clomipramine, left during her ninth week in the study, when she had reached 95% of her target weight. This appeared to be mainly due to psychodynamic 'transference' difficulties. The other two—one on placebo, the other on clomipramine—stopped their tablets during their third and fourth weeks in the study, when they had reached 82% and 80% respectively of their target weights. Both (including the patient on placebo) complained of side-effects usually associated with tricyclic antidepressants.

The mean body weights, at admission, of the clomipramine and placebo groups were not significantly different, though the placebo group were slightly lighter (Table I). Mean target weight was the same for the two groups. All the patients, including those who dropped out of the study, reached their target weights. The two groups showed no significant differences in weight gained during the refeeding programme, or in the time taken. Those who took the clomipramine spent a mean of 76 (s.d. 24) days to reach their target weights, whilst the control group spent a mean of 72 (s.d. 28) days. Those taking active medication gained, on average, less body weight each day than the placebo group, but this difference was not statistically significant. Both groups were highly active in bed both by day and by night. There were no signficant differences between the groups in these respects but a tendency for the placebo group to be more active at night (Table II).

TABLE I

Weight change in anorectic patients given clomipramine or placebo

	Clomipramine group		*Placebo group*	
	mean	*s.d.*	*mean*	*s.d.*
Mean body weight on admission: kg	40.6	4.6	37.7	5.2
Mean target weight: kg	53.93	4.22	52.4	6.15
Mean weight gain: kg	13.33	5.32	14.7	4.60
Rate of weight gain (kg/day)	0.17	0.038	0.21	0.031

TABLE II

Mean hourly activity (units of movement on motility bed)

	Nocturnal (23:00 to 7:00)	*Diurnal (7:00 to 23:00)*	*For 24 hours*
Clomipramine	97.1 ± 41.9	249.9 ± 127.1	171.5 ± 80.1
Placebo	125.2 ± 40.7	270.7 ± 100.0	197.9 ± 65.9

Mean daily energy intake on the refeeding programme was 2650 calories. When patients were allowed their own choice of food (free day), those on placebo demonstrated marked weekly variation (Fig. 1). For five such free days their mean intake was below the mean of the refeeding programme.

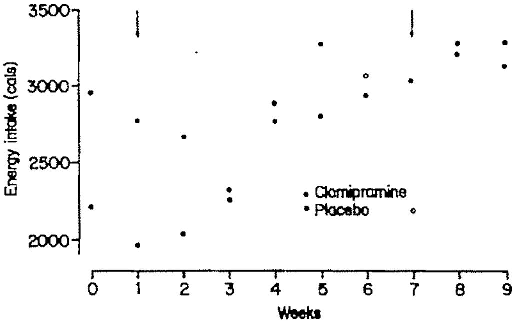

FIG 1. Mean 'free day' energy intake for clomipramine and placebo groups in each week of study, showing the statistically significant differences at weeks 2 and 8 (arrowed).

Patients in the clomipramine group were more stable in their eating habits and, except for 1 week, their mean energy intake was above the mean for the prescribed diets given on the other days.

During the second and eighth weeks of the study, the difference in caloric intake between the two groups was statistically significant (standard *t*-test), and in the first week it just failed to reach significance (Fig. 1).

Table III shows the mean analogue scale scores (and s.d.s) for the eight feelings measured. Only one—hunger—significantly differentiated overall between the two populations. For the first 2 months those taking clomipramine were significantly more hungry (standard

TABLE III
Mean analogue scale scores

	Clomipramine		*Placebo*	
	mean	*s.d.*	*mean*	*s.d.*
Hunger	48	8.3	19	6.1
Anxiety	30	5.2	26	4.7
Anger	21	6	23	5
Excitement	32	9	25	10
Sadness	38	16	51	17
Tension	42	12	31	11
Appetite	51	5	49	6.4

t-test), whilst during the last 3 weeks the two populations felt hunger similarly (Fig. 2).

Although the overall appetite scores were not statistically different, a more detailed examination (Fig. 3) of daily and weekly recordings indicates that the appreciation of appetite by the two groups was quite distinct. For the first 5 weeks those on the drug felt an increased appetite. This was statistically significant for the first 3 weeks and the fifth week (Student *t*-test). Thereafter the scores of the two groups were similar. The clomipramine group appreciated appetite as a more stable phenomenon and their reports lack the major fluctuations of those who did not take the medication.

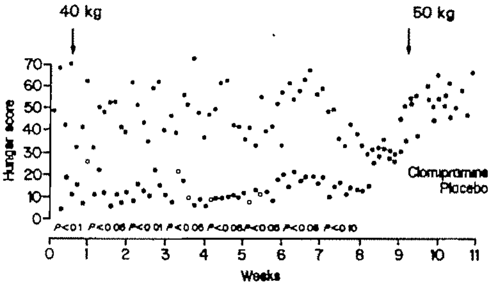

FIG. 2. Mean daily hunger scores of the two populations. Figures above tracings give mean body in kg.

At 1-year follow-up (Lacey & Crisp, 1980) there was no significant difference in body weight between the groups, though the clomipramine group (at 95.6% of target weight) was somewhat heavier than the control group (89.9% of target weight). At 4-year follow-up (1981–1982), involving personal interviews, extensive assessment was made using the original Morgan & Russell measures of outcome (Morgan & Russell, 1975; Hsu *et al*, 1979). The average score on this measure is the sum of the outcomes assessed in four areas: nutritional status, sexual adjustment, socio-economic adjustment and mental state. Ratings refer to the 6 months before assessment. There was no difference between the groups. The clomipramine group was at a mean 94.1% of target weight, the placebo group 92.7%. Mean sexual adjustment scores (which include a measure of menstruation) were 2.4 for each group while mean social adjustment scores were 3.0 and 2.5 respectively.

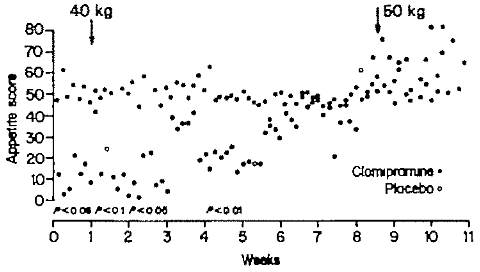

FIG. 3. Mean daily appetite scores of the two populations. Figures above tracings give mean body weight in kg.

Discussion

In this study the additive effect of clomipramine has been studied within an established in-patient programme. The latter, with its complementary behavioural and psychodynamic treatment elements is itself sufficient to enable anorectics to achieve target weight in a predictable way. However, when the behavioural constraints were occasionally relaxed in the present study the clomipramine consumption was, especially in the earlier stages of treatment, sometimes significantly associated with continued ingestion of calories sufficient to maintain such weight gain whereas, without clomipramine, this was not always the case.

Consumption of the drug was also associated with increased reported experience of hunger and appetite during the early stages of treatment. Such experience also arose in the placebo group after the half-way stage of treatment, by which time the average weight of each group would have been about 45–47 kg. This body weight is of a pubertal level and kind and associated in normal growth with a spurt in both appetite and weight gain. The first author has argued elsewhere that this experience is often the principal seed bed of anorexia nervosa in those who associate it with loss of control in respect of new-found sexuality and its consequences, and who identify this unwanted and frightening impulse with their increasing and newly constituted 'fatness'. It is therefore likely that it is experienced as frightening once again by anorectics gaining weight in the way described. Indeed, it is at this level of weight that an anorectic is most likely to drop out of treatment, especially if she and her family have not now developed some additional and psychological resources to enable her and them to live with the experience and to cope with and adjust to it.

Anorectics are known to be hyperactive and this population was probably no exception, although we do not have normative data concerning the activity of non-anorectic subjects confined to bed throughout

24 hours. Activity levels, as measured, were not affected by clomipramine.

In this study the drug was stopped at the point of reaching target weight. Up until that time it had seemed to be potentially helpful in terms of achieving weight gain, albeit unnecessary for this purpose within the established treatment programme. However, of course, the problem with treating anorexia nervosa is not so much this short term treatment as the longer term one enabling the anorectic to maintain herself at normal body weight and thereby begin to work through its consequences in a psychological sense. If we had continued to prescribe clomipramine following mobilisation and relaxation of the behavioural constraints of the in-patient programme in respect of food intake, then perhaps it would have been helpful during the remainder of the inpatient's stay (when patients usually anyway retained their body weights) and also during out-patient follow-up. In this respect both its pharmacological and its additional symbolic value in terms of the supportive effect of a 'transitional object' at a time when treatment is otherwise severely diluted in our own service, largely because of limited out-patient resources, should be borne in mind. However, we are aware that there would also have been problems with such a policy, because quite a number of patients complained of side-effects and some dropped out of the study prematurely on that account, and undoubtedly in a normal treatment setting there would have been some non-compliance.

Finally, this study invites further introspection concerning the mode of action of 'antidepressant' drugs. The first author has argued elsewhere (Crisp, 1980*b*; 1986) that the tricyclic drugs have an immediate effect on drive behaviour (e.g. foraging in association with the experience of appetite and hunger, sexual interest and activity and also generalised restlessness) and that it is this effect which enables some depressives to re-engage socially and thereby begin to interact and become less 'depressed' as the weeks go by. The present study, demonstrating the rapid impact of clomipramine on reported appetite and on actual caloric ingestion in anorectics, provides some support for this view.

The Memory Clinic

A New Approach to the Detection of Dementia

T. J. M. VAN DER CAMMEN, J. M. SIMPSON, R. M. FRASER, A. S. PREKER and A. N. EXTON-SMITH

Memory impairment is a salient and early feature of developing dementia, but in practice is often not recognised until it has reached an advanced stage. The operation described is of a Memory Clinic opened on an experimental basis at the Geriatric Research Unit, University College London, in 1983, with the aim of identifying the causes of memory impairment in the elderly, with particular reference to the early detection of dementia. It proved possible to identify a group of people with early dementia who had previously been undiagnosed, and also to reveal deficiencies in the utilisation of existing services. Memory clinics would be a valuable addition to geriatric and psychogeriatric services.

Dementia is often not detected until the mental deterioration has reached an advanced stage. Family doctors may fail to recognise it and the general public tends to accept poor memory as a normal concomitant of ageing. Thus, in many patients the diagnosis of dementia is not made until some other condition precipitates admission to hospital.

Epidemiological studies in the elderly population have shown a remarkable consistency in the prevalence of dementia. The results have been summarised in the Report of the Royal College of Physicians on Organic Mental Impairment in the Elderly (1981); some reported on the incidence of early dementia. Although it can be assumed that patients exhibiting moderate to severe symptoms will have passed through a stage of mild dementia, the diagnosis of early deterioration in these cases has presented many problems which have not been resolved satisfactorily (Kay *et al*, 1968; Bergmann *et al*, 1971; Henderson & Huppert, 1984).

The detection of organic mental impairment in epidemiological studies has usually been based on mental status questionnaires (Roth & Hopkins, 1953; Hodkinson, 1974), which test for short- and long-term memory, orientation, awareness of events and ability to count forwards and backwards. Memory impairment is a salient and early feature of developing dementia, but simple tests such as these are in themselves of restricted value for diagnostic purposes (Hinton & Withers, 1971; Hare, 1978; Whitehead & Hunt, 1982).

We outline the operation of a Memory Clinic which we opened on an experimental basis in April 1983 with the aim of identifying the causes of memory impairment in the elderly, with particular reference to the early detection of dementia. The clinic was established to provide a service for patients, their carers and general practitioners. We describe a more comprehensive approach to diagnosis than is usual, based on team investigation, and report on the first 50 patients.

Operation of the clinic

General practitioners are encouraged to refer elderly people who complain about their memory or whose friends or relatives have noticed memory problems. The team in the clinic consists of a psychologist, a physician and a psychiatrist who see the patient independently, each using his own method of assessment.

The psychologist

The psychologist usually sees the patient first to ascertain whether there is a true memory deficit. A memory problem is defined as a condition experienced by the patient which may or may not be accompanied by an objectively observed memory deficit. By means of an in-depth interview, the psychologist elicits the evidence, in terms of actual incidents of behaviour, that has led the patient to suspect that he has a memory problem, and records the earliest failures which led to this suspicion being aroused. An informant is interviewed to obtain an independent and detailed behavioural history; this is especially necessary when the patient himself cannot given an accurate account. Several factors affect the readiness with which memory problems are reported.

Two simple tests are administered initially:

A: *The Cerebral Function Test (Silver, 1972)*

This is a brief screen of various mental abilities, including memory for recently learnt material, naming, vocabulary and spatial skill. It is a short test battery which was designed to be carried out by unskilled observers and to be easily understood. To this end, the items have face validity; i.e. their meaning is obvious and the implications of failure are readily interpretable. The predictive validity of the total test score has been established by Silver and again by Ross & Horne (1977) with respect to an old person's ability to live independently. In the Memory Clinic we were not concerned with this aspect of the test but used it as a brief neuropsychological screen for indications of language and spatial deficit, low educational level and inability to learn and retain new material. The memory component, learning a fictitious name and address and recalling it after 5 min has been described elsewhere (Priest & Woolfson 1986), whose list details the administration procedure with one exception. Prior to presentation of the target material, the patient is warned that it will be necessary to recall it after 5 min. If this warning is omitted, the nature of the task is altered and it becomes more difficult. This test is similar to that included in many screening tests familiar to geriatricians and psychogeriatricians. Many of these mini-batteries are of limited use, as they focus on memory and orientation alone, omitting screens of language and spatial ability. In the Silver test, spatial ability is tested in several ways, including that first described by Isaacs (1963) using toys. We had the test materials specially made in wood so that they looked less like toys and our patients found them perfectly acceptable.

B: *The Kendrick Battery for the Detection of Dementia (Gibson & Kendrick, 1979; Kendrick et al,* 1979)

This consists of two easily administered tests, for which there are normative data. The first subtest taps memory by immediate recall, i.e. immediately after exposure of the test material, which is a card displaying a number of pictures of common objects. There are four cards, the number of objects to be recalled increasing over the series. The second part tests perceptu-motor speed and patients are required to copy lines of digits as fast as possible. The instructions for administering, timing and scoring these procedures are precise. The battery has been tested for criterion validity on groups of normal and memory-impaired old people. It yields evidence of a person's definite memory deficit but does not indicate if he is below average for a person of his age and educational level. These tests can therefore offer evidence to confirm that a person's memory problem does indeed reflect an actual memory deficit, but a diagnosis of dementia should not be made on test scores alone, in the absence of other evidence and without excluding alternative causes for the memory deficit.

If the patient fails the memory component of test A and scores in the abnormal ranges of test B, more sophisticated memory assessment is redundant, but the procedures are repeated in 6 weeks to confirm the results of the first observations.

If the patient scores in the normal range on the screening tests, more demanding memory assessments are made with particular reference to dual performance tasks and delayed recall (Randt *et al*, 1980). At this stage, it is essential to establish a baseline of memory ability with which to compare future performance, as stability or decline in this skill is critical to establishing a diagnosis. To this end, the limits of the efficiency of the patient's memory are sought. Test instruments on which the patient easily achieves near-perfect scores risk being insensitive to any future change. In this respect, the usefulness of some computer-controlled tests that we have designed is also being assessed (Simpson & Linney, 1985).

The psychologist assigns each patient to one of three categories according to the amount of evidence that is found after several visits. This grouping parallels the process by which a clinical diagnosis of dementia is finally made, i.e. based on memory deficit in the absence of another explanation. Characteristics of the patients in the three categories are:

Category 1: Clear evidence of memory deficit

(a) Memory deficit on objective tests that have established cut-off points, e.g. Object Learning Test (OLT) of the Kendrick Battery.
(b) Behavioural evidence of deficit from the reports of an informant and/or as observed during visits to the clinic.
(c) Subjective complaints about memory problems may or may not be present according to the amount of insight retained.

Category 2: Equivocal evidence of memory deficit

(a) Normal scores on the OLT although other memory tests may yield scores lower than expected for the person's age-group and IQ.
(b) Behavioural evidence from an informant and/or from observations during visits to the clinic.
(c) Subjective feelings of memory problems.

Category 3: No objective evidence of memory deficit

(a) No clear evidence of memory deficit on testing; normal scores on OLT, and performance on other tests in the expected range for a person of this age and IQ.
(b) No clear behavioural evidence from any source.
(c) Subjective feelings of memory problems.

The physician

The physician attempts to identify any extra-cerebral causes of memory loss (Royal College of Physicians, 1981; Wood, 1984) and to distinguish between acute confusion, dementia and depression. He screens for focal cerebral lesions presenting as dementia, and tries to distinguish between dementia of Alzheimer's type and multi-infarct dementia, using the Hachinski score (Hachinski *et al*, 1975). This is an 'ischaemic score' based on the different clinical features of multi-infarct dementia and Alzheimer-type dementia. Patients with a score of 7 or more are rated as probable multi-infarct dementia; those below 4 as Alzheimer-type dementia. Exceptions to this demarcation are to be found in clinical practice, and the number and clinical extent of strokes, the amount of infarcted tissue seen on CT and the presence of pseudobulbar palsy should be taken into account, and perhaps weighted more heavily (Miller *et al*, 1984). In a study of elderly demented patients who came to autopsy, the score has been shown to identify accurately patients with multi-infarct dementia or with mixed pathology (Rosen *et al*, 1980).

A careful medical history is obtained from the patient and relatives wherever possible, a full medical examination is carried out, and in the neurological examination particular attention is paid to evidence of dysphasia and parietal lobe signs.

The laboratory investigations include a full blood count, serum glucose, urea and electrolytes, creatinine, rapid plasma reagin test and treponema pallidum haemagglutination assay (TPHA) test, and liver function and thyroid function tests. Serum vitamin B12 and folate concentrations are measured only when the mean cell volume is raised. It is recognised that the yield from these tests is low when applied as a routine in the investigation of dementia (Report of the Royal College of Physicians, 1981). Other diagnostic procedures, including CT scanning, are carried out when indicated.

Special attention is paid to the drugs that the patient is taking, since it is known that several groups of drugs can impair memory and cognitive performance in the elderly. These include hypnotics and other psychotropic drugs, anticholinergic agents and certain centrally acting antihypertensive drugs (Solomon *et al*, 1983).

The psychiatrist

The psychiatrist takes a history and carries out a mental state examination. The objects, are first, to diagnose any affective disorder that may be responsible for or contributing to the memory impairment; secondly, to diagnose dementia on clinical evidence—the diagnostic criteria are those of Hare (1978), based on the Kew Cognitive Map (McDonald, 1969). Thirdly, the psychiatrist assesses the overall severity of the dementia and the future provision that the patient will require; he will have the continuing clinical responsibility for the majority of the patients. In the absence of a simple rating scale of severity that takes account of all the cognitive impairments of dementia, the various degrees of severity are characterised as below. (The validity of these categories will be tested by the follow-up studies, and it is hoped that a simple and useful clinical rating scale can be provided.)

Absent	No evidence of cognitive impairment.
Equivocal	Slight memory impairment, definitely or possibly due to affective disorder.
Minimal	Definite memory impairment *or* dubious or minimal memory impairment, together with slight nominal dysphasia.
Mild	Definite memory impairment, together with definite nominal dysphasia.
Moderate	Definite impairment of both recent and remote memory, possibly with confabulation. Moderate dysphasia (including difficulty in naming simple objects) and some failure of comprehension. Possibly some parietal features (e.g. dressing apraxia). Possibly some personality deterioration (e.g. emotional lability, paranoia).
Severe	As above, but all worse in degree and with definite personality deterioration.
Profound	As above, but all worse in degree; totally dependent on others for self-care. Little coherent communication.

Main diagnostic categories

The team members meet regularly to discuss the patients they have investigated. A diagnosis is established or, if this is not possible, a hypothesis about the likely diagnosis is formulated. The diagnostic categories for the first 50 patients (32 female, 18 male; age-range 61–90 years; mean age 75.2 years) who have been fully assessed by all three members of the team are shown in Table I.

A firm clinical diagnosis was made in 66% of patients. Of the total series of patients, 50% were dementing to some degree, and all these patients had a memory deficit in category 1. A provisional diagnosis of dementia was made in 14% of patients, and these had memory deficits in categories 1 or 2. In 10%, a diagnosis of probable affective disorder was made, and these patients had memory deficits in categories 2 or 3; the other diagnoses in 8% of patients included potentially reversible organic disorders such as polypharmacy (two patients), hyperthyroidism (one patient) and Wernicke's encephalopathy (one patient). In 10% of patients, no clinical diagnosis could be established and neither could a memory deficit be demonstrated.

Of the 25 patients who had evidence of Alzheimer dementia, the psychogeriatrician rated eight as moderately demented, 11 as mildly demented and six as minimally demented. Amongst the 16 in this group who had been referred by their family doctor, only five had already been put in touch with the psychogeriatric and community support services prior to being referred to the Memory Clinic. Neither these five nor the other clearly demented patients in this group had thus far received the level of support their condition required. These patients, with a firm clinical diagnosis of dementia, were referred to their local consultant in psychogeriatrics who provided the continuation of care. Since the Memory Clinic was established for the early detection of dementia, only those patients whose diagnosis remained in doubt were followed up in the clinic.

The memory deficit was reversible in the two patients who suffered from the effects of polypharmacy. This is illustrated by the following case reports. Drugs which can impair memory are asterisked.

Case 1 (other diagnosis; memory deficit category 2)

Miss K.A., a 78-year-old woman, was referred to the Memory Clinic in December 1983. The referral had been initiated by her relatives, with whom she lived. In 1975 she had been firmly diagnosed elsewhere as suffering from cerebral atrophy and her relatives had been attending the relatives' support group of The Alzheimer Disease Society for several years. She had equivocal evidence of memory deficit (category 2). On the Kendrick Battery for the Detection of Dementia, she scored in the normal range but close to the cut-off point in both of the subtests (memory/visuospatial speed). She had some impairment of recent memory, and her scores on the Raven's Matrices indicated that her intelligence was below average for her age.

Past medical history: hypertension; hysterectomy.

She was taking oxprenolol hydrochloride*, hydralazine hydrochloride, Lasikal, allopurinol, flurazepam*, piroxicam and medroxyprogesterone. Her medication was gradually reduced until she took only medroxyprogesterone 100 mg *b.d.* and Navidrex-K, one three times per week. She was seen at regular intervals and, as the drugs were reduced, her memory tests improved. The psychogeriatrician did not consider her demented.

Diagnosis: memory deficit due to polypharmacy.

TABLE I
Clinical consensus diagnosis

	Memory deficit Category 1	Category 2	Category 3	
Firm diagnosis				
Alzheimer-type dementia	25 (9)			
Multi-infarct dementia	3 (1)		1	66%
Other diagnoses	2	1 (1)	1 (1)	
Provisional diagnosis				42%
Probable affective disorder		3 (1)	2	
Probable dementia	3	4 (1)		
No diagnosis			5 (2)	

Notes: The vertical axis describes the clinical diagnosis and the horizontal axis the degree of memory deficit. Figures in brackets are numbers of patients for whom referral was initiated by the patient or carer. Patients with other diagnoses, provisional diagnosis or no diagnosis are being followed up (42%).

Case 2 (other diagnosis; memory deficit category 1)

Mrs M.S., a 66-year-old woman, was referred by her family doctor in August 1984 because of increasing forgetfulness. She had been diagnosed elsewhere as suffering from dementia and her CT scan had been reported as showing small diffused areas of low density.

Past medical history: in 1952 she was overweight and treated with amphetamines which caused overexcitement and resulted in her being prescribed chlordiazepoxide which she had taken since. She had also been diagnosed as having Parkinson's disease and had been started on anti-parkinsonian drugs. In addition, she had a history of depression, hypertension and more recently of low back pain. Her medication consisted of Moduretic, carbamazepine*, Diphenal* (diphenihydantoin 100 mg plus phenobarbital 25 mg per tablet), benzhexol*, Buflomedil, Hypnocedon* (a sleeping tablet), chlorpromazine*, phenobarbitone*, diazepam* and biperiden hydrochloride*. Chlordiazepoxide* had been discontinued 2 days prior to her being seen in the Memory Clinic.

On examination she was fully orientated. She had scoliosis of the thoracic spine, but otherwise there were no significant physical abnormalities. She initially had clear evidence of memory deficit (category 1). Her performance was below normal on two memory tests and she became exceedingly upset and confused when required to learn a new task. She was diagnosed as having extensive osteoporosis of the thoracic and lumbar spine and was treated with physiotherapy and paracetamol. She was gradually weaned off all other drugs and improved both mentally and physically. The psychogeriatrician did not consider her to be demented.

Diagnosis: memory deficit due to polypharmacy.

Most of the other patients, 42% of the total series, are being followed up in order to confirm or refute the original diagnosis with particular reference to the diagnosis of early dementia.

Source of referral

In the total series, 26 patients had been referred directly by their family doctors and eight from other hospital departments. The other 16 patients had referred themselves, or their carers had asked the doctor to refer them. Of those who came directly or indirectly via their family doctors, some had not sought medical advice until the disease was far advanced; in other cases the doctor did not seem to be aware of the community support available.

As Table I indicates, there were larger numbers of self-referrals in those with memory deficit category 1 than in categories 2 and 3. Moreover, the 10 self-referred patients in this group had not received any support until they came to the clinic.

Discussion

Several studies have shown that a medical care system that depends upon the self-reporting of illness is severely handicapped in terms of the early detection of disease (Williamson *et al*, 1964; Gruer, 1975). This has particularly deleterious consequences in the elderly. In a study in three general practices in Edinburgh, Williamson *et al* (1964) found that 28% of the elderly patients were demented, but that the condition had not previously been recognised in over four-fifths of the cases.

In our study, it was disconcerting to find that many patients who were clearly demented had not been referred to the appropriate community support service; it was also instructive to learn how difficult it may be for a busy family doctor to recognise an early memory deficit. It is probably hard for a doctor to acknowledge such problems in a patient whom he has known for some years and who retains a good social facade, particularly if the patient is known to be of relatively high intelligence and to have held a responsible position in society. The results give support to Thompson's view (1985) that dementia is a latent condition, often detectable only by challenge.

---

* indicates drugs which can impair memory.

The introduction of a new service (e.g. the opening of a geriatric day hospital) often brings to light deficiencies in existing services. We certainly found this to be the case after the Memory Clinic had been in operation for a few months. The Report of the Royal College of Physicians on Organic Mental Impairment in the Elderly (1981) emphasises that the present *ad hoc* crisis style of management of dementia is unsatisfactory; instead there should be a readiness to seek out problems and to respond promptly to patients' needs. Criteria which diseases should fulfil if screening in the general population is to be attempted have been stipulated by Acheson (1963) and by Wilson & Jungner (1968). Recently, Cooper & Bickel (1984) have argued that the criteria also apply to the early detection of dementing disorders in old age. It is generally recognised that for screening a single sign should carry with it a high probability that the disease is present, and eliciting the sign should be simple, economical and unobjectionable to the subject. Both these criteria are fulfilled by dementia. In the Memory Clinic, we have used memory deficit as a marker for dementia, and the assessment of this deficit is based on the history, observation and simple objective testing.

Ideally there should be reasonable prospects for cure of the disease: this does apply to the mental deterioration which can result from polypharmacy and to those with 'pseudodementia' due to affective disorder. However, in the practice of geriatric medicine, cure is not in general the sole aim of treatment, but rather early detection is a preliminary to intervention aimed at reducing disability and postponing the need for institutional care. Bergmann (1979) has drawn attention to the difficulties in making the diagnosis of early or mild dementia. He emphasises the importance of defective memory and early behavioural impairment in the development of dementing syndromes. He also stresses the need for follow-up, since in one epidemiological study (Kay *et al*, 1968) it was found that 30% of patients diagnosed as probable early dementia were not demented when reassessed 3–4 years later.

We have described a team of three different specialists each assessing the patient from a particular aspect. However, the focus of assessment should be on the different tasks involved, not on the different professionals represented in our clinic. These tasks are: the collection of evidence of memory deficit, the identification of detectable causes of this deficit, the detection of underlying depression, and the counselling and management of the patient and the carer(s). All these tasks could be carried out by one suitably qualified person, but in practice, at least two people should be involved to increase the reliability of the overall assessment.

The value of the Memory Clinic can be considered under three headings:

Practical value

It offers a facility to investigate people with memory problems and to attempt to arrive at a correct diagnosis, including the revision of the original diagnosis if found to be incorrect; to establish a diagnosis in patients suffering from the early stages of a dementing illness with a view to improving the patient's management; to treat curable causes of memory loss; and to control psychiatric symptoms.

Educational value

The general public and all health care professionals need reminding that memory failure is not a normal concomitant of old age. Older people in whom suspicion of mental impairment arises or where memory loss is a subjective or objective complaint, should be investigated. Clinics to which early cases can be referred, such as the Memory Clinic, would increase awareness that screening should be undertaken. Suitable screening tests are available and should be administered routinely by all professionals coming into contact with old people. A test which is particularly sensitive to severity of memory deficit is the ability to recall recently learnt new material after an interval (Graham-White *et al*, 1969; Erikson & Scott, 1977). The material should contain at least five items which are to be recalled after an interval of 5 min during which the patient is prevented from rehearsing by involvement in other tasks. The patient should be warned about the need for subsequent recall. This type of test, the recall after a brief interval of a fictitious name and address, is included in many geriatric assessments, e.g. the Mental Test Score (Roth & Hopkins, 1953) and the Cerebral Function Test (Silver, 1972).

Research value

Since the clinic offers follow-up over time to selected patients, it will be possible to describe more accurately the natural history of the various dementing illnesses. A group of patients with early dementia can be identified, from which suitable subjects for trials of potential therapeutic agents may be recruited. If such an agent should be developed, it is more likely to be effective in the early stages of dementia.

Conclusion

This pilot project has brought to light deficiencies in the utilisation of existing services and has confirmed the point made in the Report of the Royal College of Physicians (1981) that a readily accessible and integrated service is essential in order to arrive at a correct diagnosis in patients with early dementia and to facilitate their management. Although one of the aims of the Memory Clinic is to provide a service to family doctors, many people previously unknown to the health service referred themselves or were referred by their doctor only after prompting by others caring for the patient. We believe that memory clinics could be a valuable addition to the geriatric and psychogeriatric services within the NHS and so provide a better system of management for the vast number of elderly demented patients projected for the future.

Chronic Schizophrenic Disorder
I. Psychophysiological Responses, Laterality and Social Stress

C. WHITE, J. FARLEY and P. CHARLES

Bilateral palmar skin conductance and heart rate were measured throughout a series of psychological tests and during both sitting and ambulant social interactions in 14 right-handed men with chronic schizophrenic disorder and 12 healthy volunteers matched for age and handedness. Miniature radio telemetry equipment was used to collect the physiological data. The schizophrenic group was effectively unresponsive to 70-dB auditory stimuli, while all but one of the control group responded and habituated to a nil response by the tenth tone in sequence. The schizophrenic group showed some evidence of increased skin conductance activity at rest, and in socially demanding conditions skin conductance level and variability were increased in the right hand. The present group of electrodermal 'non-responders' was not in general autonomically under-active. Asymmetry of skin conductance activity during social interaction may be a characteristic of chronic schizophrenic disorder.

A number of theories concerning schizophrenic symptom formation have implicated arousal as an important source of primary dysfunction or as a factor involved in exacerbation of the disorder (Kasanin, 1932; Mednick, 1958; Fish, 1961; Lynn, 1963; Venables, 1968; Mirsky, 1969; Ax *et al*, 1970; Epstein & Coleman, 1970; Flekkoy, 1975; Lapidus & Schmolling, 1975; Farley, 1976). The evidence concerning a possible arousal dimension and schizophrenic disorder has remained contradictory with many findings to suggest either excessive or reduced physiological activity (Lynn, 1963; Depue & Fowles, 1973; Jordan, 1974; Venables, 1977; Bernstein *et al*, 1981; Gruzelier & Manchanda, 1982).

One possible explanation for the conflicting evidence, suggested by old and recent reports (Gruzelier & Venables, 1972, Venables, 1977; Gruzelier & Manchanda, 1982), is that in schizophrenic groups there is a bimodal distribution of physiological responsiveness, particularly to low intensity stimuli. Although some attempts to replicate this finding have been largely unsuccessful (Toone *et al*, 1981; Zahn *et al*, 1981), much evidence has supported it (Depue, 1976; Patterson, 1976; Deakin *et al*, 1979; Straube, 1979; Bernstein *et al*, 1981). Several studies suggest that in schizophrenic groups electrodermal responsiveness to tones reflects general physiological, and possibly emotional, responsivity (e.g. Gruzelier & Venables, 1972, 1974; Gruzelier, 1976; Straube, 1979).

Another possible reason for the lack of conclusive results may be that such procedures do not measure responses to meaningful events. The experimental methods used to explore putative changes in diffuse activation have, with few exceptions (e.g. Schooler & Zahn, 1968; Tarrier *et al*, 1979), employed responses to standardised sensory stimuli as indices of physiological activation.

The present investigation had two linked objectives. The first was to compare autonomic activity under circumstances which imposed relatively sustained demands on the subject with responses to standard laboratory procedures. The second objective was to test the hypothesis that social activity in people with schizophrenic disorder is associated with abnormal autonomic responses (Wing & Venables, 1962; Venables, 1968), reflecting either excessive activation or inhibition. In order to rate some social abilities and impose sufficient social stress over a short period, we asked subjects to mime in front of an audience of two people.

We were particularly interested in physiological responses to social interaction and stress, because social dysfunction is important as a component of both schizophrenic deficit states and premorbid rating scales. In addition, social incapacity has been cited as an index of poor outcome (Kokes *et al*, 1977; Johnstone *et al*, 1979). The evidence suggesting that important life events and critical expressed emotion in the families of schizophrenic subjects affect the course of the disorder has strengthened the impression that sustained social stress is an important determinant of relapse.

Asymmetry of autonomic patterning in schizophrenia has assumed prominence in recent years (Gruzelier & Venables, 1974; Gruzelier & Manchanda, 1982). In developing our equipment, the opportunity was taken to record skin conductance (SC) from both sides.

Method

Patients were identified initially by hospital diagnosis and the notes were reviewed. Selection was according to Feighner criteria for schizophrenia (Feighner *et al*, 1972), but all except one of the patients appeared to have had CATEGO features of core schizophrenic disorder (Wing *et al*, 1974) at some time in their clinical career and all had had positive schizophrenic features within the previous 6 months. Twelve were in-patients. Control subjects were selected from members of the public who responded to advertisements for participants and were matched for age. Those with a history of psychological disorder in the previous 10 years or cerebral trauma, or who were taking medication of any kind which might affect the results were excluded. All subjects were paid for participating.

Each subject attended one session. After being introduced to the experiments and being given an explanation of the procedures and equipment, subjects were asked if they agreed to take part. None refused at this stage, although some patients had refused when approached on the ward. The miniature telemetry equipment and electrodes were then attached, every effort being made to keep the subject relaxed. The subject then sat alone in a comfortable chair in a dimly lit, quiet room for the first part of the session which lasted about 60 min. Communication with the experimenter took place via a microphone and loudspeaker to the side of the chair. Another loudspeaker was placed behind and 90 cm above the subject's head for the presentation of tones. A 35-cm colour television was placed to the subject's left and used to display reminders of what the tasks involved. A new message was displayed for each task. All subjects were tested for visual and auditory acuity before taking part.

Bilateral palmar SC measurements were made throughout the session using miniature telemetric equipment with a a resolution of approximately 0.001 μS and a SC range between 50 and 0.04 μS (White & Charles, 1983). One radio transmitting unit was attached to each forearm. Silver–silver chloride electrodes, 9 mm in diameter, were attached to the thenar and hypothenar eminence of each hand using collodion to form a seal around the edge of the electrode. Beckman electrode gel was injected into the electrode chambers. Although this gel is not isotonic, we found that agar-agar gel dehydrated over a period of 2 to 3 h, was unevenly distributed and had other potential disadvantages (Venables & Christie, 1980). Careful comparison of results with Beckman gel or 0.05-M NaCl agar-agar using the present equipment (data available) indicated that the only significant effects of the hypertonic solution were to elevate SC level and to prevent a slow downward drift in SC level over time. Since the aim of the present investigation was to compare groups of subjects, the absolute SC levels are not of critical importance.

SC level was sampled by computer at a rate of 10 Hz. ECG signals from electrodes placed over the subject's sternum were also monitored telemetrically. Heart rate was measured using a QRS peak detector interfaced to the computer system. The physiological data were displayed on a high resolution graphics screen during collection and recorded continuously on floppy disk with time markers every 10 s. A system with two linked computers recorded the physiological data in order to provide continuous collection and storage. A third computer was employed to control psychological procedures whose timing was also stored. A sound recording was made of each session with a time marker recorded on one track of the stereo tape. This permitted the sound replay to be synchronised with the display of SC data during analysis. The microphone was sensitive enough to detect deeper breaths and larger movements of the limbs and trunk. Room temperature was maintained at a comfortable level above 20°C.

The relatively formal psychological procedures occupied approximately 50 min and consisted of: simple reaction time, 5 min sitting quietly, 8 min sitting with a sequence of 10 auditory stimuli, the determination of critical flicker frequency, two flash threshold and set index, a sustained attention test, and a second period of rest with 6 tones. Only physiological results will be reported here.

Before either tone sequence, the subject was told that he should sit quietly for about 10 min, and that he should relax as much as possible without falling asleep. He was also informed that during the later stages of this period there would be occasional tones over the loudspeaker but that they should be ignored as far as possible. A message on the television screen also instructed the subject to ignore any noises. Each 70-dB, 1000-Hz tone was of rapid onset and offset, with rise and fall time of <2 ms and a duration of 500 ms. Tones were spaced at pseudorandom intervals between 30 and 50 s with a mean inter-stimulus interval of 40 s. The sequence of intervals was the same for all subjects.

The later part of the session was designed to provide a series of increasingly stressful social interactions, although a friendly and uncritical atmosphere was maintained throughout. After the third tone of the second series of tones, an experimenter entered the room quietly without looking at the subject and sat in a chair. At the end of the sequence of tones several minutes later, the experimenter introduced himself and said that he would like to ask some questions about how the subject got on with the tests, but before that he had to go out for a moment. He returned after 1 min with a board and a pen and sat down again in the chair, and discussed how the subject had got on in the tests in a semi-structured interview. The subject then read aloud a children's standard comprehension task and answered four questions. After a slight pause, the experimenter said: "The last thing we would like you to do is to pretend to carry out some simple daily activities without using words. Before we do that I am going to fetch somebody else." He went out of the room, waited 30 s and returned with a second experimenter. The light was then turned on, the subject was asked to stand up and the television screen was turned towards him so that experimenters could not see the display.

The subject was then instructed that he would see the topics of his mimes on the television screen and that he should act them without speaking. When he understood what he had to do, there was a delay of about 1 min. The subject then carried out three mimes whose titles have been chosen as relatively easy to perform but susceptible to several interpretations. The first two titles were selected from a list of eight possible activities from daily life such as slicing bread or washing up. The third mime was one of four affects, either anger, fear, sadness or disgust. During the mime performances, the experimenters pretended not to identify the topics so that subjects performed the mime for up to 60 s.

In the analysis of the data, SC responses to the series of 70-dB tones were assessed visually by two experimenters and accepted if they had an onset between 1 and 3 from onset of the stimulus. Peak latency, amplitude and half decay time were calculated for each peak. Thirteen sections of the experimental session, each of 30 s duration, were selected for analysis with the start times in Table I. Before analysis, all physiological recordings were inspected by eye using a high resolution graphics display of both SC channels and heart rate. Within each of the 13 sections, the following SC parameters were calculated: mean SC level for left and right hands in μS and log μS, standard deviation for mean levels in left and right hands, the sum of the deflections in positive or negative direction during the section in each hand (trend), the mean difference in SC level between the two channels, positive and negative peak deflections of more than 2% deviation from baseline (peak count), mean peak amplitude on each side, and cross divergence between the two channels.

TABLE I

Timing of 30 second sections selected for analysis with times from start of first procedure in brackets

(1) 4 min after start of sitting quietly. (8 min)
(2) 2 min before end of tone sequence. (15 min)
(3) 35 s before experimenter's first entry. (60 min)
(4) 5 s after experimenter's entry.
(5) 30 s after start of discussing session.
(6) 10 s after start of reading aloud.
(7) 5 s after start of comprehension questions.
(8) Seated after mime procedure mentioned.
(9) Preparation for miming. After standing. (66 min)
(10) Explaining mime procedures. (30 s after section 9).
(11, 12, 13) 10 s after start of mime 1, 2, 3. (70 min)

The cross divergence measure was developed in order to estimate detailed differences in patterning of SC activity between the two sides. It was calculated by taking the difference between each successive pair of 10-Hz data points in each hand, dividing that difference by the SC level of the first value of the pair, and calculating the mean of the absolute difference between the derived left and right side values for the 299 samples. Lack of divergence is represented by zero: larger values represent increasing divergence.

TABLE II

Details of subjects in the schizophrenic group

Age	*Duration of history (years)*	*Medication (total daily dose for oral medication)*
21	5	Oral flupenthixol 9 mg, chlorpromazine 300 mg
23	3	Depot fluphenazine 25 mg weekly, haloperidol 60 mg

The heart rate data were in the form of inter-beat intervals in milliseconds and these required conversion to beats per minute (60 000/ms count). Mean beat frequency and standard deviation were calculated for each section. Occasional signal loss or highly deviant responses which might have been due to defects in signal transmission were eliminated after visual assessment on the high resolution graphics display.

Histograms of multiple samples from all the variables were assessed by eye for normality of distribution and, if there was doubt about the distribution, they were subjected to analysis for goodness of fit to normality using the χ^2 statistic.

The levels of statistical analysis for the electrodermal variables and heart rate included: differences between groups for mean values across the 13 samples and across the two basal and later social sequence (sections 3–13), analysis of trends across 13 samples, and sequential sample by sample analysis for differences under the varying experimental conditions. One- or two-way analysis of variance, with repeated measures analysis when appropriate, was employed.

The mean, s.e.m. and range of age in the two groups were similar (control group: 40.5 ± 3.93 years, range 25–61; schizophrenic group: 37.7 ± 3.57 years, range 21–61) and all subjects were right-handed. Eight members of the control group and all members of the schizophrenic group were male. Some clinical characteristics of the schizophrenic group subjects are given in Table II.

Results

Of the subjects in the schizophrenic group, electrodermal responses to the tones in the initial tone sequence occurred on one occasion in each of three subjects (after tones 1, 3 and 9 respectively) but otherwise no responses to tones were seen. In the control group, clear electrodermal responses were seen in 11 out of 12 subjects, one of whose responses failed to habituate by the tenth tone, and a steady decline in SC response amplitude was observed in responding subjects. Responses were also absent in all subjects in the schizophrenic group during the later tone sequence when only five of the control group had electrodermal responses to the tones.

Group mean results for electrodermal variables and heart rate across the 13 sections are shown in Table III. No major differences between the groups were found among the electrodermal variables, but trends towards increased coefficient of variability and cross divergence (higher values) were seen in the right hand of the schizophrenic group when compared with the control group.

TABLE IV

Two-way repeated measures analysis of variance (group × hand) of lateralised electrodermal variables across the basal two sections (d.f. = 1, 1) and the 11 sections in the social sequence (d.f. = 1, 10)

1. SC = skin conductance; CV = coefficient of variation (s.d./mean).
2. Peak frequency in counts/30 s with a 2% deflection from baseline criterion.

(a) a significant interaction between groups and hands in skin conductance level, reflecting a higher mean right-hand value in both groups,
(b) a weakly significant effect for groups in coefficient of variation due to a greater variability in the schizophrenic group,
(c) a significant hands effect for peak amplitude due to increased peak amplitude in the right hand of both groups.

The difference between groups in peak frequency in the basal sections reached a 0.1 level of probability.

In the analysis of the later, social sequence (sections 3–13), strong effects for groups, hands and their interaction were found for skin conductance level and variability, reflecting the marked elevation of skin conductance level and variability in the right hand of the schizophrenic group. Peak frequency was not increased in either group or hand. An increase in peak amplitude on the right side in both groups was reflected in the significant effect for peak amplitude for hands, with a trend to a group × hands interaction.

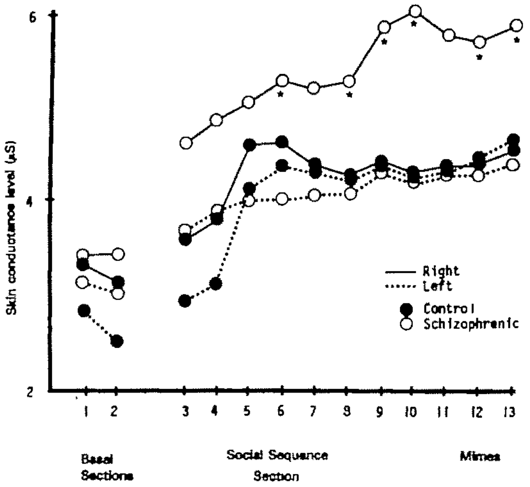

FIG. 1 Group mean skin conductance levels in 13 sections in control and schizophrenic groups. Significant difference between hands in schizophrenic group: $^*P<0.05$, using repeated measures analysis of variance.

Within groups, analysis of changes in the electrodermal variables across the 13 sections using one-way repeated measures analysis of variance yielded significant changes ($P<0.02$) in the control group for all variables except peak amplitude. The results were similar in the schizophrenic group except that no significant effect was seen for peak frequency or coefficient of electrodermal variability.

Evaluation of section by section changes in SC level in either hand using one-way repeated measures analysis of variance (Fig. 1, Table V) indicated that in the later sequence (sections 3–13) significant mean increases in both hands occurred in the control group after the experimenter came into the room (between sections 3 and 4) and when starting to discuss the session (between sections 4 and 5), matched by similar but weaker trends in the schizophrenic group.

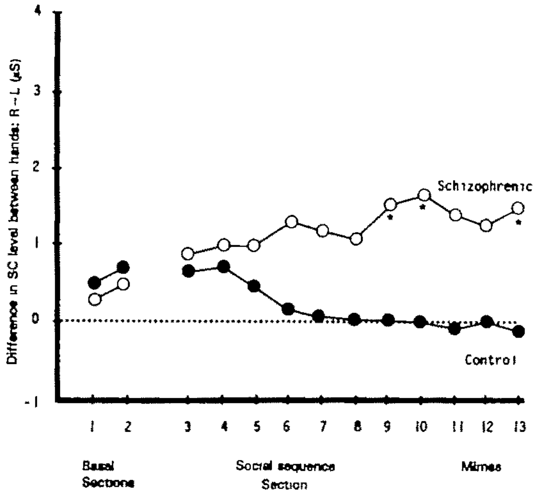

FIG. 2 Group mean differences in skin conductance level between hands in control and schizophrenic groups. Right hand minus left. Significant difference between groups using one-way analysis of variance: $^*P<0.05$.

A large increase in SC level in both hands was observed in the schizophrenic but not the control group when standing in anticipation of miming (between sections 9 and 10), while small but similar increases were seen in both groups between the second mime (of a daily activity) and the mime of an emotional state (between sections 12 and 13).

Section-by-section analysis of the change in difference in SC level between hands using repeated measures analysis of variance indicated no statistically significant effects in the control group but significant increases in the schizophrenic group in right-hand level over left when starting to read aloud (between sections 5 and 6: $F\,[1, 13] = 6.10$, $P=0.03$) and after standing up in anticipation of miming (between sections 8 and 9: $F\,[1, 13] = 17.56$, $P=0.001$). Figure 2 shows the tendency to equalisation of SC level in the two hands in the control group in later sections with a divergence between the hands in the schizophrenic group, reflected in a difference ($P<0.05$) in SC level between hands in the schizophrenic group in several of the later sections (Fig. 1). Between sections 3 (before the experimenter's entry) and 7 (comprehension questions), an electrodermal left shift was seen in nine members of the control group and a right shift was found in ten members

of the schizophrenic group, the others showing small changes in the opposite direction.

Mean cross divergence was increased in the two basal sections in the schizophrenic group (control group 0.253 ± 0.049 nS per sample, schizophrenic group 0.651 ± 0.172 nS per sample: F [1, 24] = 4.36, $P=0.05$), but a trend in the same direction was weaker in the social sequence (control group 0.750 ± 0.098 nS per sample, schizophrenic group 1.076 ± 0.165 nS per sample: F [1, 24] = 2.75, $P=0.11$]. There was no significant difference in any of the electrodermal measures between the small group of women and the men in the control group.

The mean heart rate of the schizophrenic group was significantly higher ($P<0.01$) than that in the control group in all sections, but the amount of change in heart rate under varying circumstances did not differ between the two groups.

Discussion

Since we were breaking new ground by using radio telemetry for measurement of SC in a group of people, it was necessary to establish the reliability of the system. In general, reliable and sensitive measurement of SC and heart rate under ambulant conditions proved possible. Subjects quickly became used to wearing the small transmitter units.

Our aims in extending the range of techniques of psychophysiological measurement in this way were to compare the autonomic responses of a schizophrenic group in a social setting with responses to standardised low intensity tones, and to examine the possibility that people with chronic schizophrenic disorder might show excessive excitatory or inhibitory responses to social stress. The virtual absence of responses to tones in the schizophrenic group, other than in one subject who could be classified as a fast habituator (Patterson & Venables, 1978), was unexpected but provided the opportunity to assess other autonomic response characteristics of a 'non-responder' group.

There was no evidence to suggest that non-responsivity to low intensity tones in our sample was associated with reduced SC responsivity or variability in the schizophrenic group while sitting at rest or during the socially active sections approximately 1 h after the start of recording. Indeed, a number of findings indicated greater physiological activity than in the control group: a bilateral increase in SC variability associated with a trend to increased peak frequency when sitting early in the session, a trend towards bilaterally increased SC variability in some of the socially demanding sections even after compensation for differences in SC level, an overall increase in SC level and peak amplitudes on the right side in the later sections, and increased heart rate throughout.

Shorter-term autonomic responsivity in later sections in both groups varied with circumstances but was not generally increased or reduced in the schizophrenic group. The major exception was the electrodermal response which took place during the preparation for miming. This is difficult to evaluate because in the schizophrenic group electrodermal activity, particularly on the right side, changed when the subjects stood up. No comparable alteration was evident in the control group, and changes in heart rate in the groups were similar and at least partly attributable to alteration in posture. As SC level on the right in the schizophrenic group continued to rise in section 10 whilst miming was further explained, it seems probable that the changes from section 8 to 10 were mainly psychological in origin, but a greater separation of standing up and preparation for miming would have been preferable. Our pilot studies with healthy volunteers and hospital patients had led us not to expect effects on electrodermal activity due to standing up.

Contrary to our prediction, the sections when subjects mimed repeatedly in front of two experimenters were not accompanied by bilateral evidence of abnormal autonomic responses in the schizophrenic group when compared with controls. This might have reflected lack of social engagement, but participation and mime ability were not impaired in the schizophrenic group (White *et al*, 1987). Since the bulk of experimental evidence suggests that unmedicated subjects with schizophrenic disorder show raised SC levels (Lader, 1975; Gruzelier & Hammond, 1978; Bernstein *et al*, 1981), it is probable that SC level was reduced in our sample by neuroleptic treatment. Even so, the prediction of augmented responsiveness to social stress was partially correct since electrodermal activity was increased on the right side.

The most striking findings were the persistently increased heart rate and the electrodermal laterality effect. Elevated heart rate in schizophrenic groups is perhaps the most consistent finding in the literature (Depue & Fowles, 1973; Lader, 1975; Zahn *et al*, 1981) and may in part be ascribed to medication.

The electrodermal laterality effect was seen most clearly when the shifts in SC level between the start and end of the social section in the two groups were compared (Fig. 2). The effect began during questioning about the tests and reading aloud, while the subject was still seated, and was enhanced during the miming section.

The lateralised difference in SC level between the groups is consistent with previous reports (Gruzelier, 1973; Gruzelier & Manchanda, 1982), in which enhanced autonomic responsiveness to tones on the right in people with schizophrenic disorder has been the most frequent finding. Such right-sided enhancement of responses to tones was recently found by Gruzelier & Manchanda (1982) to be associated with 'negative' or Bleulerian symptoms. Bernstein *et al* (1981) reported that larger right-hand responses to tones were associated with increased EEG alpha blockade in the left hemisphere, indicating a physiological hemispheric activation effect, but that this link was not specific to a schizophrenic diagnosis. Gruzelier & Venables (1974) have also reported a sustained right-hand shift in electrodermal level during a psychological task with an increase in right-hand excess as SC levels increased. Other reports of sustained situational measures (e.g. Tarrier *et al*, 1979; Sturgeon *et al*, 1981) have recorded SC activity from one hand only, usually the left hand, and have not assessed lateral asymmetry.

The interpretation of the electrodermal laterality effects depends in part on evidence concerning anatomical lateralisation of central nervous control of electrodermal activity. Suggestions that limbic structures in the temporal lobe could mediate lateralised autonomic effects remain unsupported by relevant evidence in animals or man (see review by Toone *et al*, 1981), but the recent demonstration of left-sided elevation of dopamine concentrations in the amygdala of post mortem brains from schizophrenic subjects (Reynolds, 1983) might reflect relevant limbic changes.

Lateralisation of influences from other sites must also be considered. Manipulation of the cerebral cortex in cats, either in the 'limbic' area on the medial surface of a cerebral hemisphere (Isamat, 1961) or in the premotor area 6 (Schwarz, 1937), can produce preferential alterations in electrodermal activity on the contralateral side. In man, Gruzelier & Manchanda (1982) cited neurosurgical evidence in favour of contralateral electrodermal modulation from frontotemporal sites. Furthermore, early reports clearly suggested contralateral influences on sweating from the frontal, premotor cortex (Kennard *et al*, 1934; Kennard, 1935; Netsky & Starr, 1948). Despite the general lack of consistency in findings of asymmetrical SC activity (Freixa i Baque *et al*, 1984), it would appear inappropriate to exclude an anatomical basis for contralateral SC control at a cerebral level.

If contralateral control of electrodermal does occur, then our data would support suggestions of abnormal cerebral activity in the dominant hemisphere in people with schizophrenic disorder.

In interpreting the non-responsiveness to tones in our schizophrenic group, several factors require consideration. The bulk of reports indicate that non-responsivity to low intensity tones correlates with generally reduced autonomic activity (Gruzelier & Venables, 1972; Gruzelier, 1976; Straube, 1979). Since our data are inconsistent with those reports and since we had no responding schizophrenic group for comparison, conclusions from our results can only be tentative. We have no reason to suspect that methodological factors affected responding to tones. In other work, non-responsivity to low intensity tones has not been accompanied by reduced responsivity under other standardised stimulus conditions (Gruzelier *et al*, 1981), or by altered EEG changes after tone stimuli (Bernstein *et al*, 1981). Gruzelier & Manchanda (1982) recently commented that responsivity to tones reflects factors which are relatively specific to the tone response procedure, while sustained changes in SC level are more likely to reflect arousal.

Another pertinent issue is that of the physiological need for increased pseudomotor activity on hands under some circumstances. Some of the determinants of SC responses appear to be emotional, and others more cognitive or anticipatory of motor function (Germana, 1969; Bernstein, 1979; Maltzman, 1979; O'Gorman, 1979; Lang *et al*, 1980). There does appear to be agreement in the literature that electrodermal responses to intermittent abrupt events, such as tone stimuli, depend on sensory input analysers which are largely unconscious and, at least at times, cognitively sophisticated. Therefore, such responses may be sensitive to cognitive disruption as well as to putative general changes in activation, and so theoretically unsuitable as a measure of arousal in people susceptible to schizophrehnic disorganisation. The reports by Straube (1979) and Bernstein *et al* (1981), suggesting that non-responding to tones was associated with increased cognitive disorganisation in a schizophrenic group, are compatible with this hypothesis.

With regard to the effect of medication, although it remains possible that a bimodal distribution of responding is somehow revealed by medication, sustained treatment with neuroleptics appears not to modify transient responses to low intensity auditory stimuli and previous results have in general not supported a pharmacological interpretation of electrodermal non-responding (Venables, 1977; Straube, 1979; Bernstein *et al*, 1981).

The incongruity between normal or increased levels of electrodermal activity and increased heart rate and non-responsiveness to tones in our schizophrenic group may be explained by inadequacy of the tone response procedure as an index of arousal in schizophrenia. Sustained differences between the groups under socially active conditions, as used in the present investigation, appear to be appropriate and practicable indices of a possible underlying dimension of arousal and may indicate the time course of excessive psychophysiological responses, despite the relatively poor standardisation of experimental conditions when compared with tone presentation procedures.

The hypothesis that social dysfunction is a result of excessive activation is supported at least partially by our results. If SC activity is controlled from the contralateral side of the brain, the data may support the hypothesis of dysfunction in the dominant hemisphere in at least some patients with persistent schizophrenic disorder, but further information is required to substantiate such a suggestion.

Chronic Schizophrenic Disorder

II. Reaction Time, Social Performance and Arousal

C. WHITE, J. FARLEY and P. CHARLES

Reaction time, set index, critical flicker frequency, two-flash threshold, a sustained performance task and psychophysiological parameters from people with chronic schizophrenic disorder ($n = 14$) and a control group ($n = 12$) were analysed to assess the association between arousal, attentional dysfunction and social dysfunction in schizophrenia. Shorter reaction time, rated ability to mime and, in the schizophrenic group, scores on Venable's ward activity scale correlated with each other. In the schizophrenic group, prolonged reaction time latency correlated positively with skin conductance level in the right hand and negatively with skin conductance variability in the left hand, the latter being in the opposite direction to that for the control group. The results may provide support for the hypothesis that lateralised cerebral dysfunction is associated with performance deficits in people with chronic schizophrenic symptoms.

Several investigations have indicated that, despite the achievement of reliability in the measurement of 'positive' symptoms of schizophrenic disorder, such features have only weak predictive value for clinical and social outcome (Hawk *et al*, 1975; Vaillant, 1978; Johnstone *et al*, 1979; Kendell *et al*, 1979). Although outcome has limitations as an index of psychopathology (Strauss & Carpenter, 1977; Stephens, 1978), chronicity remains of clinical importance and may reflect severity of disorder. The best predictor of poor outcome other than previous chronicity appears to be poor social adjustment (Kokes *et al*, 1977; Strauss & Carpenter, 1977; Johnstone *et al*, 1979; Ciompi, 1980). Therefore, elucidation of the factors underlying social difficulty, and possibly negative symptoms, may be of value in understanding the nature of schizophrenic psychopathology.

The objectives of the present investigation were first to assess social performance in people with chronic schizophrenic disorder using two procedures: Venables's (1957) ward activity scale and the subject's ability to mime; and secondly to evaluate the relationship of scores on those measures to peripheral and cerebral measures of arousal, reaction time latency and attention. Other than miming, the procedures were selected from those in the literature which have shown reliable performance deficits in people with schizophrenic symptoms (Shakow, 1962; Kornetsky, 1972; Nuechterlein, 1977).

Method

Each subject attended one session which lasted about 90 min. The subject sat alone in a comfortable chair in a dimly lit, quiet room during the relatively formal procedures. Communication with the experimenter took place via a microphone and loudspeaker to the side of the chair. A 7-cm square array of 16 high brightness light-emitting diodes (LEDs) (total luminance 400 mcd) was placed on a table in front and slightly to the right of the subject, approximately 60 cm from his eyes, with a small dimly lit LED in the centre of the array for visual fixation. A 35-cm colour television was placed to the subject's left and used to display reminders of what the tasks involved. A new message was displayed for each task.

On either arm of the chair there was a bounce-free, Hall effect switch. These were used during all the active procedures for reaction timing and choice indication. The subjects were instructed to rest their index fingers lightly on the switches when performing a task and to tap them quickly when making a response. During the reaction time tasks the dominant hand was employed. All subjects were tested for visual and auditory acuity before participation.

Bilateral skin conductance and heart rate were recorded telemetrically throughout the session as described elsewhere (White *et al*, 1987).

The early part of the session occupied by formal psychological procedures lasted approximately 60 min and consisted of the following sequence:

1. simple reaction time,
2. 5 min sitting at rest,
3. 12 min sitting with ten intermittent tone stimuli,
4. critical flicker frequency,
5. two-flash threshold,
6. set index,
7. a sustained performance task,
8. 5 min sitting with six tone stimuli.

A short reaction time procedure was placed at the start of the sequence in order to familiarise the subjects with a simple task. The instructions were to watch the lights and to press the response button as quickly as possible when they lit up. Several practice attempts were given. The stimulus sequence consisted of 16 illuminations of the light array (rise time $<20\ \mu s$) with an inter-stimulus interval (ISI) of either 2, 4 or 7.5 s in a pseudorandom order.

Both critical flicker frequency (CFF) and two-flash threshold (TFT) were measured using two procedures: (a) a staircase procedure in which the sequence started at clear separation of flashes and progressed through threshold to a fused stimulus and back to the initial inter-flash interval. (b) A successive approximation procedure (Taylor & Creelman, 1967), in which changes in flicker rate were presented in a stepped sequence determined by the computer, following rules which allowed the subject repeatedly to cross his threshold from either a flicker or fused direction until he reached a criterion step size which terminated the sequence.

During the CFF procedure, subjects were instructed to keep their gaze fixed on the small central LED and to respond with the right-hand button if the lights were flickering when they were lit and with the left-hand button if not. They were instructed to make a choice on every occasion, but the timing interval and display were terminated if no response had occurred within 5 s of stimulus onset. Mark to space ratio in the flicker display was unity. The visual fixation LED flickered with the rest of the display but was left on during the ISI.

After several practice attempts, the first sample of responses was collected using the staircase procedure. An approximate threshold was selected from the staircase procedure as the flicker interval perceived as just flickering in both the ascending and descending directions, and used as the starting interval for a successive approximation procedure which followed. In this latter section the subject completed four runs of which the first and third started at a flicker interval 20 ms above threshold and the second and fourth 20 ms below. If the starting interval in a run was less than 20 ms, the minimum increment was changed to 500 μs and the starting points were 10 ms above or below threshold. The terminating criterion for each run was a step size of 1 ms. Four estimates of threshold were obtained in this fashion and the mean of these taken for further analysis. If the subject became stuck in a series of widely swinging oscillations, the experimenter had the facility to change the terminating criterion. In practice, the need for this did not arise with CFF.

The procedures used to determine TFT were similar to those for CFF with an initial staircase sequence followed by a forced choice successive approximation procedure. The subject was instructed that the task was similar to that for flicker but that only two flashes would be presented and he had to watch carefully for the warning signal when the central LED went out and for the flash stimuli 1 s later. If two flashes were visible, he was to press the right-hand button, and if only one flash was seen, the left. The mean duration of each flash was approximately 50 ms, but the stimulus sequence (on–off–on) was adjusted by the computer so that total duration was constant at 140 ms, and light intensity was adjusted on a trial-by-trial basis by the computer to compensate for flash duration so that perceived light intensity was constant. The formula for this adjustment was determined by the experimenter during the development of the programme.

The CFF and TFT data were recorded as critical flicker and two flash intervals (cycle length) rather than frequency (interval = 1000/Hz). In the set index procedure (Rodnick & Shakow, 1940; Nuechterlein, 1977), reaction time measurements were made using the same apparatus as in the early reaction time section, but the test was divided into two halves. In the first half, 40 light stimuli were presented with a balanced but pseudorandom order of ISIs with ten presentations at each ISI. In the second half, the same number of stimuli were presented with the ISIs in blocks of ten of 2, 4, 7.5 and 15 s. Each subject received the same sequence of ISIs. The subject was told that in the first half the intervals between the onset of lights would be unpredictable, but that during the second half the intervals between the lights would be the same for ten stimuli at a time and that he could use this to anticipate when the next stimulus would occur. A reminder of this was given at the start of the second half of the task. Failures to respond were counted and excluded from analysis. Mean response times for each ISI in each half were calculated and the set index for each subject calculated according to the formula derived by Rodnick & Shakow (1940).

In the sustained performance test, subjects were presented with either the word 'LEFT' or the word 'RIGHT' on the television screen, with a display period of 100 ms and an ISI of 1100 ms, for 60 trials. They were instructed to react only to the word right (target stimulus) which occurred on 20 occasions. Response and error rates and mean reaction times were calculated. This procedure was designed to be similar to the continuous performance test (Kornetsky, 1972), but simplified to allow for the relative lack of practice time. Subjects practised until they achieved correct responses on several trials.

The sequencing of the social sections has been described elsewhere (White *et al*, 1987). In the later stages of the sequence, subjects performed three mimes whose titles were selected so as to be relatively easy to perform but susceptible to multiple interpretations. Two experimenters attempted to guess the mime titles, but pretended not to recognise the mimes so that the subject had to continue to act for up to 60 s. The two experimeters scored each of three mimes for each subject for mime ability (how recognisable was the mime? Score 1–3) and amount of movement (1–4), and overall for expressed embarrassment and difficulty (1–5) and expressed affect (1–5). Mime ability and movement scores were the total of the ratings for each of three mimes.

Clinical features were assessed using the Present State Examination (Wing *et al*, 1974) and the Krawiecka scale (Krawiecka *et al*, 1977). Venables's (1957) ward scale for activity and sociability was completed by members of the nursing staff for 11 of the 12 in-patients.

All the grouped data were assessed for goodness of fit to normality and between-group comparisons for individual measures were carried out using analysis of variance. Mean values are given as mean ± s.e.m. Correlations were performed on data from both groups combined and each group separately using Pearson's product moment correlation coefficient. For the mime ability ratings, the mean between-raters concordance score was calculated according to the method suggested by Cicchetti (1976): agreement = 1, disagreement by one = 0.5, by two = 0.

Results

Details of the subjects and the psychophysiological data are given in White *et al* (1987). Both group mean simple reaction time at the start of the session and the set index value were greater in the schizophrenic group than in the control group (Table I). The correlation between mean initial simple reaction time and set index was 0.82 ($n=12$, d.f. $=10$, $P<0.01$) in the control group and 0.73 ($n=14$, d.f. $=12$, $P<0.01$) in the schizophrenic group, suggesting considerable consistency in individual levels of performance within groups.

TABLE I

Mean reaction time latency and set index scores in control and schizophrenic groups

	Control group mean	Control group s.e.m.	Schizophrenic group mean	Schizophrenic group s.e.m.	F	P
Reaction time:						
ms	237.9	17.0	446.6	93.9	4.43	0.04
Sex index	482.4	45.6	1082.5	282.7	5.22	0.03

Many participants found the TFT procedure more difficult to perform than CFF estimation, and this difficulty was reflected in the fact that six subjects in the schizophrenic group were unable to complete the two-flash testing, reducing the schizophrenic group size to eight. The group mean critical flicker and two-flash threshold intervals (CFI, TFTI, 1000/Hz) are shown in Table II. The between-group mean CFF levels were not significantly different for the staircase procedure, but for the successive approximation procedure the CFI in the control group was significantly shorter, reflecting improved discrimination. None of the group mean levels in TFTI was significantly different from others (Table II).

Within-group correlation coefficients for results of the staircase and successive approximation procedures for CFI and TFTI were 0.94 and 0.89 respectively in the control group ($n=12$) and 0.60 ($n=14$) and 0.74 ($n=8$ for TFTI) for the schizophrenic group. Within-group correlations between mean CFI and TFTI scores derived from the two staircase and successive approximation procedures were 0.27 in the control group ($n=12$) and 0.54 in the schizophrenic group ($n=8$).

Mean error rates in the control and schizophrenic groups on the sustained performance test were 0.5 ± 0.28 ($n=12$) and 8.1 ± 2.23 ($n=14$), but the data in the schizophrenic group were bimodally distributed. The schizophrenic group was divided on the basis of error scores (less or more than five errors respectively) on the sustained performance task. The mean reaction time of the two groups was 462.1 ± 195.1 ($n=8$) for the group with few errors and 433.6 ± 73.9 ($n=6$) for the group with many errors. Respective mime scores were 12.1 ± 2.0 and 12.5 ± 1.15.

For the mime ratings, the mean concordance score was 0.81 ± 0.04. The mean mime ability scores in the two groups were similar (Table III), but the amount of motor activity during miming in the schizophrenic group was less than that of controls.

The mean Present State Examination (PSE) score for psychotic and neurotic symptoms in the schizophrenic group was 10.1 ± 4.1, with a mean psychotic symptom score of 4.9 ± 1.9. The mean symptom score on the Krawiecka scale was 3.57 ± 0.9. The scores on Venables's ward activity scale for the ten questions were totalled for each subject for further use (positive score represents more activity and sociability).

In order to test the hypothesis that mime score and reaction time reflected a similar aspect of psychological function, their correlation coefficient was calculated in both the combined group and each group separately using mean reaction time during the set index procedure (80 trials). In the combined group data, a correlation coefficient significantly different from zero was found for reaction time during the set index procedure with mime score (-0.43, d.f. $=24$, $P<0.05$), while in the control and schizophrenic groups the respective figures (Table IV) were -0.53 (d.f. $=10$, $P<0.1$) and -0.44 (NS). Assessment of scatter plots of the combined data and of values for each group and recalculation after elimination of outliers showed clearly that the interaction was consistent across and within the groups.

TABLE II

Mean critical flicker interval and two-flash threshold interval in control and schizophrenic groups by staircase and successive approximation procedures

	Control group			Schizophrenic group			
	n	mean	s.e.m.	n	mean	s.e.m.	
CFI: ms							
Staircase	12	32.0	2.13	14	31.4	2.35	NS
Successive approx.	12	26.7[1]	1.44	14	30.7	1.97	NS
TFTI: ms							
Staircase	12	39.5	3.5	8[2]	44.1	7.9	NS
Successive approx.	12	39.2	5.6	8	31.3	13.0	NS

1. Mean CFI in control group using the successive approximation procedure significantly shorter than that using the staircase procedure in the control group: F (1, 11) $=20.11$, $P=0.001$.
2. Six members of schizophrenic group failed to complete the TFT procedure.

TABLE III
Group mean scores on rated aspects of miming

	Control group *n = 12*		*Schizophrenic group* *n = 14*			
	mean	*s.e.m.*	*mean*	*s.e.m.*	*F*	*P*
Mime ability	14.0	0.67	12.3	0.99	1.91	0.17
Difficulty	1.29	0.30	1.07	0.27	0.50	0.82
Movement	18.42	1.22	11.29	1.10	18.97	0.00
Affect	4.58	0.61	4.43	0.51	0.39	0.84

Further evaluation of possible associations with this reaction time/mime interaction was possible in the schizophrenic group using the ward activity scale scores which correlated 0.53 (d.f. = 9, $P<0.1$) with mime ability, −0.66 (d.f. = 9, $P<0.05$) with initial reaction time and −0.50 (d.f. = 9, NS) with mean reaction time during the set index procedure.

Since the major difference between the groups in the physiological data (White *et al*, 1987) was of increased skin conductance (SC) activity in the right hand under socially active conditions, we hypothesised that high right-hand SC level would interact negatively with performance measures. The correlation between grand mean SC level in the right hand and reaction time in the combined group data of 0.37 (d.f. = 24) was significant at the 0.05 level. This was reflected in a similar although non-significant correlation in the schizophrenic group (Table IV). Appraisal of the scatter plot for electrodermal right shift between sections 3 and 13 with reaction time in the schizophrenic group suggested that the correlation coefficient (0.40, NS) underestimated the strength of interaction. Electrodermal right shift between the start and end of the social sequence (White *et al*, 1987) correlated more strongly with the reaction time result at the start of the session ($r = 0.58$, d.f. = 12, $P<0.05$). The mean right-hand SC level in subjects in the schizophrenic group with reaction time latencies during the set index procedure above or below 450 ms ($n = 7$ in each group) were 6.23 ± 1.07 and 3.94 ± 0.64 respectively ($F[1, 12] = 3.31$, $P<0.1$, with only one subject overlapping from each group).

An unpredicted difference between the groups was that SC variability on the left in the schizophrenic group correlated positively with mime ability and negatively with reaction time while the reverse relationship was present in the control group (Table IV).

The relationships between CFF and performance measures were contrary to predictions, since longer CFI (lower frequency) correlated with better mime and reaction time scores in the control group and better mime scores in the schizophrenic group (Table IV). In the control group, heart rate correlated positively with mime ability and showed a trend to negative correlation with reaction time. No such interaction was seen in the schizophrenic group.

TABLE IV
Correlation matrices for control and schizophrenic groups

HR										1.00

Significantly different from zero: *$P<0.1$, **$P<0.05$. Significant difference between groups, $^{\dagger}P<0.05$. For each group, d.f. = n-2. Abbreviations: Age: age in years, RT: mean reaction time during set index procedure, Mime: mime ability score, CFI: critical flicker interval, SCL: skin conductance level on left, SCR: skin conductance level on right, CVL: coefficient of variation of skin conductance on left, CVR: coefficient of variation of skin conductance on right, LS: change in mean difference in skin conductance level between sides from start to end of social sequence, HR: heart rate. The physiological variables other than LS are the grand means for each individual across 13 sections.

Discussion

Reaction time and set index scores differentiated reliably between the groups, and the stability of reaction time scores through the session suggested that they were reliable characteristics of the individuals. These results are therefore consistent with previous work where reaction time delay has proved one of the very few reliable associates of schizophrenic disorder (Yates, 1973; Nuechterlein, 1977; Steffy, 1977). Prolongation of reaction time has been found to correlate with schizophrenic disorganisation (Rosenthal *et al*, 1960). It should be noted that the initial reaction time procedure was very brief (16 trials), while the set index procedure required sustained attention over 10-min periods (80 trials) and effectively acted as a sustained performance task.

As the present results for TFT appeared to be less reliable than those for CFF, the CFF results were employed in further analyses. The low correlation of CFF and TFT in the control group suggested either that they are not similar measures or that factors other than flash discrimination sensitivity *per se* played a role in the determination of results. The most obvious reason for impaired performance in the TFT procedure is that, even when a warning signal is given, the subject has to attend very carefully to see the two flashes, whereas during CFF estimations the subject is able to contemplate the stimulus at length before making a decision. This difficulty may have been enhanced by the present procedure since flash durations were considerably shorter than those used elsewhere (e.g. Gruzelier & Venables, 1974).

A high proportion of the schizophrenic group commited many errors on the sustained performance task. We hypothesised that since the ISI was 1.1 s, this was primarily due to slow reaction time. However, mean set index reaction time was not slowed in the group making numerous errors compared with that making few errors. It is possible that performance was affected by factors other than reaction time or sustained attention, particularly since relatively little time was given to training.

Mime assessment was employed because we hypothesised both that social abilities *per se* may be deficient in people with schizophrenic disorder (Farley, 1976) and that abnormal arousal function was a determinant of social dysfunction. It was necessary to assess directly abilities that might form part of social behaviour while subjects were under stress. We know of no other reported means of doing this. The present mime assessment procedure with relatively small numbers of subjects appeared to yield good levels of inter-rater agreement with little formal training. The lack of group mean difference in mime scores was unexpected, since we had predicted that people with chronic schizophrenic disorder would find this section difficult.

In assessing the significance of correlations between variables, the relatively small numbers of subjects compared to the number of variables prevents conclusions from being more than tentative. However, the data do suggest hypotheses which merit further evaluation.

In contrast to the apparent absence of correlation between the sustained performance task and reaction time measures, mime scores correlated with fast reaction time in both groups. Furthermore, Venables's ward activity scale scores correlated positively with mime scores and negatively with reaction time in the schizophrenic group. Correlation between reaction time latency and ability to mime in the human population appears not to have been reported previously and raises questions concerning the importance of the attributes of the nervous system which underlie reaction time performance in social behaviour. The positive interaction with the ward scale scores for the schizophrenic subjects suggests that a unitary dimension of behavioural arousal may be involved.

With regard to interactions between performance and physiological dysfunction, the elevated SC level in the right hand reported in White *et al* (1987) correlated with longer reaction time latency in the schizophrenic group, supporting the hypothesis suggested by the results of Gruzelier & Manchanda (1982) that elevated right-hand electrodermal activity is associated with slowing.

An unanticipated observation was that the interaction between SC variability on the left side and performance was significantly different between the groups. In the schizophrenic group, better performance was associated with increased SC variability on the left side. However, increased SC variability on the left and high SC level on the right did not generally occur in the same individuals in the schizophrenic group, as indicated by the lack of correlation between lateral shift or right-hand SC level and left-hand SC variability, suggesting that separate effects, possibly lateralised, may be present for SC level and variability.

In the control group, mime score and reaction time performance appeared to correlate with fast heart rate and low CFF which may imply that better performance is associated with high peripheral autonomic activity and low cerebral arousal. A similar effect for heart rate was not seen in the schizophrenic group, but a trend to correlation of mime score with low CFF was evident.

A simple interpretation of the data indicating impaired reaction time in schizophrenic subjects with high SC level in the right hand is that of underlying dysfunction in the left cerebral hemisphere in at least a subgroup of people with schizophrenic syndromes (Gruzelier & Flor-Henry, 1979). However, further information is required before interpretations of lateralised indices of arousal and schizophrenic disorder can be made with any confidence, in view of both the lack of detailed information concerning the localisation of control of electrodermal level or variability (White *et al*, 1987) and the indications here and elsewhere (e.g. Crider & Lunn, 1971; Depue & Fowles, 1973) that at least two aspects of electrodermal activity (level and variability) may differ in their significance for psychophysiological function.

Our results suggest that a social stress procedure such as the present one may provide a useful means of evaluating determinants of social dysfunction when suitable physiological and performance measures can also be assessed within a short time. Lateralised SC variables may relate to altered psychological performance in people with schizophrenic disorder in ways which are relatively complex but still measurable.

Acknowledgements

We are grateful to Dr Nicholas Perl, Senior Psychologist, Bedford District, who played an important part in the early stages of the investigation and provided useful advice and encouragement; to the staff of Fairfield Hospital for providing facilities and for readily given help with many aspects of the project; to Mrs J. Guthrie for much valuable assistance; and to Mr D. Juett, Senior Physicist, Addenbrookes Hospital, for extensive advice and help with electronic equipment. The Wellcome Foundation provided a Research Fellowship for C.W., supported P.C. and funded an equipment grant. Some funding for equipment was also provided by the Schizophrenia Fellowship.

Influence of Husbands on the Outcome of their Agoraphobic Wives' Therapy

K. OATLEY and D. HODGSON

Of 30 agoraphobic married women undertaking home-based behaviour therapy, 15 each had a female friend as co-therapist and 15 had their own husband as co-therapist. At 12 months follow-up, women spent a mean of approximately 40 minutes a day more outside the home alone than at baseline. Women assisted by female friends made somewhat more behavioural gains than those assisted by husbands. Women in both groups whose husbands had been more depressed 2 months after the beginning of therapy did less well at 6 months. Husbands who become more depressed may retard their wives' progress in therapy, but the effect was small, and was outweighed by other considerations.

Hafner (1977*a*,*b*) claimed that many husbands of agoraphobic women become depressed when their wives' phobic problems improve in therapy. He argued too that a husband who becomes symptomatic can thereby induce his wife to relinquish therapeutic gains, and to relapse back into her agoraphobic condition.

Family therapists (e.g. Minuchin & Fishman, 1981) have proposed that within a family a circular homeostatic pattern may occur in which a set of roles helps to maintain symptoms in one family member, while the symptoms tend to maintain family members in their roles. Applying this to families with agoraphobia, the dependent role of a more fearful partner may be complemented by a role of helpfulness in the more mobile partner, and this complementarity (cf. Bateson, 1935) may help to maintain agoraphobia. Simultaneously, symptoms help maintain a dependency in which both partners have an interest.

According to this argument, attempts to displace the family from its equilibrium by therapy are likely to be resisted by forces which tend to restore homeostasis in the couple.

The therapy used by Hafner (1977*b*) in his study of 30 marriages in which wives were agoraphobic was based on 12 hours of group exposure to feared situations within a 4-day training period, with questionnaire measures taken at baseline and at intervals during the following year. He divided patients into a more hostile and a less hostile set. The more hostile patients did less well. Husbands of this set became more hostile during the follow-up period, and their mean psychiatric symptoms increased, but then decreased again when their wives partially relapsed. In some husbands, depression and jealousy reached alarming levels. Milton & Hafner (1979) studied 18 patients in a similar design. Patients less satisfied with their marriages did less well, and their marital satisfaction decreased.

These findings suggest that families may resist therapeutic change, but the increase in husbands' psychiatric symptoms and the relapses of the patients were small and not statistically significant. Moreover, Hafner's conclusions have been questioned: Cobb *et al* (1984) found no decrease in marital satisfaction during agoraphobic wives' therapy, and were sceptical that spouses influence recovery from agoraphobia.

The home-based therapy of Mathews *et al* (1977, 1981*b*) for agoraphobia enabled a further test to be made of the homeostatic hypothesis of marriages in which the condition occurred. In this procedure the client undertakes outings of graded difficulty, and is in charge of her own therapy. Her husband is recruited as co-therapist, and the professional therapist acts mainly in a consultative role, making a small number of visits.

The present study was an independent trial of the treatment programme of Mathews *et al*, with measures taken at baseline and 2, 6 and 12 months. Either the subject's husband or a woman friend was randomly chosen to act as co-therapist. We tested Hafner's hypothesis of resistance by spouses, and included behavioural measures. We aimed to ascertain also whether the therapy of Mathews *et al* is effective where patients recruit friends rather than family members to assist them.

Hypothesis 1. The principal hypothesis was that there would be a difference in outcome between women with husbands as co-therapists and women with female friends as co-therapists. We could not predict which condition would do better, because Hafner's hypothesis allows two different directions of effect.

In one direction, acting as co-therapist might provide a new role for a husband to replace the one he was losing as his wife's caretaker. This might counter depression associated with loss of his previous role, diminishing any tendency to retard his wife's progress. Hence, women whose husbands were acting as co-therapists might do better.

In the other direction a husband who wished to keep his wife at home would be more able to retard therapy in a co-therapist role. Co-therapists outside the client's marital relationship might enable the client to do better.

Hypothesis 2. In direct replication of Hafner's 1977*b* report, as wives become more independent, husbands might experience change in their marital equilibrium and suffer symptoms. As Hafner implied and as would be expected from a major role loss (Oatley & Bolton, 1985), these symptoms would be mainly depressive. Hence husbands' depression scores were predicted to rise at 2 months, and perhaps fall again later. Moreover, if acting as co-therapist did provide husbands with a new role, then those who were co-therapists would become less depressed than those who were not co-therapists.

Hypothesis 3. Clients whose husbands became depressed at 2 months would be expected to go out less by 6 months. There would be a negative correlation between husbands' depression scores at 2 months and their wives' behavioural improvement at 6 months.

Hypothesis 4. According to the homeostatic theory, marriages in which wives felt controlled by their husbands might be more resistant to change. Hence, there would be a larger negative correlation between husbands' early depression and wives later behavioural scores than in marriages in which wives felt less controlled.

Hypothesis 5. We derived an index of hostility to try and replicate Hafner's 1977*b* finding that more hostile clients made poorer progress than those who were less hostile.

Method

Subjects

Subjects were drawn from 59 women in Brighton, Eastbourne and North London who volunteered for the study: 24 were contacted via self-help organisations for phobics, 31 got in touch with us after articles in the local press, and four were referred by GPs.

Criteria for acceptance were that the subjects were aged 18–70 years; had been married or in stable heterosexual cohabitation for at least 3 years; had been agoraphobic for at least 3 years; and had both a husband (or male partner) and a woman friend prepared to help. They had to be literate (in order to fill in forms and read the therapy booklets), be free of physical disability, and not be receiving treatment for agoraphobia other than tranquillisers or anti-depressants prescribed by their GP.

Agoraphobia was defined using the criteria of DSM-III (American Psychiatric Association, 1980) of (a) fear and avoidance of being alone or in public places, or of places where escape is difficult because of sudden incapacitation; (b) severely constricted daily activities because of inability to leave home alone, or to enter public places; and (c) condition not due to an obvious primary major depressive episode, obsessional–compulsive disorder, paranoid disorder or schizophrenia. In addition we administered the Leeds Self Assessment of Anxiety Specific Scale, range 0–18 (Snaith *et al*, 1976). This has a case threshold between 6 and 7. All but one of the 30 subjects who undertook the trial were above case threshold on this scale, with 26 of them having scores of 12 or above.

We explained the programme to the 39 women who met the criteria. We said we would decide randomly whether their husband or their woman friend would be co-therapist for them, but that to take part they had to make sure that both were willing to help. Six further women decided against going ahead after learning more about the programme or because their husbands refused to be available as co-therapists. This left 33 cases. They were assigned randomly, two to each condition in blocks of four, either to a condition in which their female friend would be their co-therapist (FF group), or to one in which their husband would be their co-therapist (HB group).

TABLE I
Patient characteristics in each treatment group

	FF group (*n* = *15*)	*HB group* (*n* = *15*)
Mean age (years)	45	42
Mean duration of agoraphobia (years)	18	14
Proportion on tranquillisers (%)	60	80
Proportion on anti-depressants (%)	7	7
Proportion on both types of drug (%)	20	7
Proportion who had previously received psychological help to overcome agoraphobia (%)	33	60
Social class (Registrar General's classification)		
I & II (%)	53	46
III & IV (%)	46	46
V (%)	0	7

In the FF group, two subjects dropped out early in therapy because going out made them too anxious. Another subject was excluded from the HB group because we discovered that she had become partially blind as a result of diabetes, and had been getting her husband to fill in the assessment forms for her. This left 15 subjects in each group. We collected complete data up to 6 months. We followed up all 30 couples for 12 months, though at 12 months one FF and one HB couple would complete only the Leeds scales (see below) but no other instruments.

Table I shows the characteristics of the subjects. The severity and duration of symptoms were similar to those of clinical samples (cf. Buglass *et al*, 1977; Mathews *et al*, 1981*a*).

Assessment methods

Three main measures were taken at baseline, at 2 months, at 6 months (i.e. end of therapy), and at 12 months (i.e. 6-month follow-up). A Response to Treatment Questionnaire was taken at 12 months.

Behavioural diaries

Behavioural diaries were modified from those of Mathews *et al* (1977, 1981*a*). After detailed discussion, a patient listed activities which for her were 'safe' (i.e. did not cause anxiety even on a bad day). The patient was then asked to record in the diary everything else she did. She kept the diary every day for 2 months, and then again for 2 weeks at the 6-month and 12-month assessment points.

An Items score was derived from a generalised hierarchy of 15 items which provoke anxiety and avoidance by agoraphobics. At the lower end of this hierarchy, items 1 and 2 are, respectively, the patient spending up to 30 and 60 minutes outside a particular safe room in her house. These were only applicable to a few people. Items 3, 4, 5 and 6 are leaving home alone for at least 5, 15, 30 and 60 minutes, respectively. The next items, also to be accomplished alone, are (7) local shops, (8) main shops, and (9) trips on public transport. Next are items of outings up to 4 hours, which may be accompanied, and in order of increasing social constraint: (10) accompanied outings (e.g. car trips or walks with a spouse), (11) visits (e.g. to friends, or visits of others to the patient's home), (12) visits to pubs, cafes etc., (13) attending public assemblies such as doctor's, parents' meetings at school, cinema etc. Finally there are two items about longer outings; (14) more than 4 hours, and (15) more than 8 hours—away from home on visits of various kinds during which the patient may be accompanied. Details of content analysis and scoring developed for these diaries are given by Oatley and Hodgson (in prep.). Item scores range from 0 to 15.

Diaries at each assessment point (baseline and 2, 6 and 12 months) were analysed to determine how many items on this hierarchy had been accomplished. To score one item the patient had to record its performance twice during a 5-day assessment period that included a weekend.

A subsidiary diary measure was the total amount of time away from home during these 5-day periods. Diary entries are made each day after performance. Hence, these scores may be more valid than retrospective questionnaire measures of phobic symptoms.

Leeds Scales for the Self Assessment of Anxiety and Depression

The Leeds self-report questionnaire (Snaith *et al*, 1976) was completed by all patients and husbands at each assessment point, with no consultation between each other. It has 15 statements, each describing a symptom of anxiety or depression to be rated on a four-point scale and scored 0–3. We used two principal measures as described by Snaith *et al*; (a) for patients the Specific scale of diagnosed anxiety, which we will call Clients' Leeds Anxiety Scores, and (b) for husbands, the General scale of non-diagnosed depression, which we will call Husbands' Depression Scores. Each scale of six items has a range of 0–18.

Dyad repertory grids of relationship

To try and predict in which marriages therapy might go more or less well, we administered a dyad repertory grid (Ryle & Lunghi, 1970), to patients and husbands. Supplied constructs were 'Feels guilty about, Looks after, Exerts control over, Gives in to, Blames, Is irritated by, Depends on', to be rated on seven-point scales for the marital relationship and relationships with parents. Patients and husbands were asked to complete grids without consultation, though we said they could discuss them afterwards if they wished.

Two criteria derived from baseline grids were used to predict who would be most resistant to therapy. One was of patients who felt controlled by their husbands. The criterion of high control by husband was a score of 4 or more at baseline on the construct 'Exerts control over' as applied to the husband. Over all 30 subjects, irrespective of co-therapist, this criterion gave a split of 16 wives who felt control was high and 14 who felt control was low.

The other criterion, to parallel Hafner's index of hostility, selected patients scoring 5 or more at baseline on either or both of the constructs 'Blames' and 'Is irritated by' applied to their husbands. This gave 14 high hostility patients and 16 low hostility patients, irrespective of co-therapist.

Principal components analysis of the whole grids will be reported elsewhere.

Response to Treatment Questionnaires

Response to Treatment Questionnaires were distributed at the 12-month follow-up meeting. Patients were asked to complete them not while the therapist was present but later, and return them by post. Ratings on five-point scales were made on the following questions: overall satisfaction with the programme, change in being able to go out alone, change in being able to go out accompanied, change in depression, change in anxiety, change in optimism about being able to overcome agoraphobia. The five-point scales were of the form (1) very dissatisfied, very much less able to go out, etc., (2) dissatisfied etc., (3) no change, (4) satisfied, etc., (5) very satisfied, etc. Clients were also asked for details of any other therapy or self-help they had undertaken during the 12 months.

To reduce bias we did not check any Leeds or grid measure until after the 12 month interviews.

Therapy programme

Therapy was based on the home-based treatment of Mathews *et al* (1977, 1981*a*). Instructions to client and co-therapist were provided in booklets (Mathews *et al*, 1981*b*), supplemented by our written introduction and by the relaxation audiocassette of Sharpe (1976).

The authors were the therapists. After working under supervision with four pilot cases using this therapy, one of us (KO), with 8 years' experience of conducting groups and 3 years' of giving individual interpretive and cognitive therapy, saw eight clients, and the other (DH), with 6 years' experience working behaviourally with self-help groups, saw 22.

Before the first meeting we had decided by telephone or letter if acceptance criteria were met. The random choice of husband or woman friend as co-therapist was then made.

At the first visit, lasting 1.25 hours, the therapist saw the patient with her husband, irrespective of whether she had been assigned to the FF or HB group. We told the couple whether husband or woman friend would be acting as co-therapist. We described the programme and the role of the co-therapist, and explained that as well as giving the therapy we were doing research to see how husbands or friends might help in therapy and to see what feelings husbands and wives had in the course of therapy. A history and demographic information were collected.

Husband and wife were asked to complete the Leeds scales and the repertory grid forms. The patient was helped to prepare a safe list for her diary which was left so that she could make daily entries for a baseline week. We left the treatment booklets and the relaxation tape. We also left two copies of a contract recording agreement to the therapy, signed by the therapist.

We discussed the implications of therapy for the couple's relationship, and how it might mean substantial changes for both of them. We said that they should only go ahead after they had both read both booklets and discussed the programme together. If they decided to go ahead then the wife and the co-therapist should sign the contract form.

The client was asked to practice relaxation twice a day using the tape, but to make no other changes in her life until the next meeting, a week later. To acquire a baseline measure of activity, she was asked to record in her diary her performance of all activities not on her safe list.

Subsequent visits lasted an hour or less, and were at 1 week and 1, 2, 6 and 12 months, with phone calls at 2 weeks and in order to make appointments for visits.

Up to 6 months the co-therapists were asked specifically to attend meetings, which were largely concerned with describing the therapy as specified by Mathews *et al*, discussing progress, and advising patient and co-therapist. Some patients who had a woman friend as co-therapist had their husband also present. At 2, 6 and 12 months we also collected the measures, which were typically sent by post before visits.

At 6 months we discussed the long-term plans of the patient, and enquired about marital difficulties if this had not been raised spontaneously. We discussed further help where such difficulties had occurred.

At the 12-month follow-up visit we saw the patients and their husbands for further discussion and closure.

Two patients, one each in the FF and HB group, started further therapy near the 6-month point. At 12 months we referred two other couples, one in each of the FF and HB groups, for marital therapy.

Results

As may be seen from Figs 1 and 2, both FF and HB groups of patients improved on mean behavioural Items and Leeds anxiety scores by 6 months, and the improvement was sustained at 12 months. Separate analyses of variance were performed on the scores for each measure. In the Items analysis the within-subjects improvement over time was significant ($F=15.85$; d.f. 3, 78; $P<0.001$), although neither the difference between the FF and HB groups, nor the group × time interaction were significant. (P-values of 5% or less will be regarded as significant in this paper.) Improvement in Leeds anxiety scores over time was significant ($F=13.75$; d.f. 3, 84; $P<0.01$), although again neither the between-group effect nor the group × time interaction were significant.

On both measures most of the improvement was accomplished in the first 2 months, and these gains were sustained thereafter. This was confirmed by significant *a posteriori* *t*-test between baseline scores and subsequent

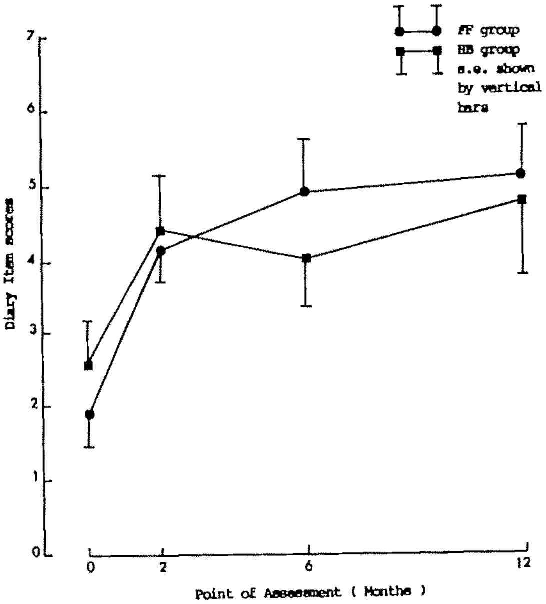

FIG. 1. Means and standard errors of Items scored on a generalised hierarchy, as assessed from behavioural diaries, by 15 patients with female friend (FF) co-therapists, and 15 with husband (HB) co-therapists, at baseline (0), after 2 and 6 months of therapy, and at a 12-month follow-up.

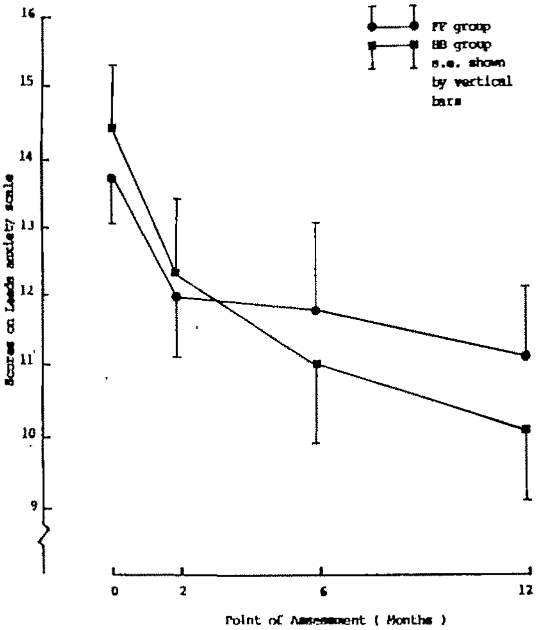

FIG. 2. Means and standard errors of Leeds anxiety scores by 15 patients with female friend (FF) co-therapists, and 15 with husband (HB) co-therapists, at baseline (0), after 2 and 6 months of therapy, and at a 12-month follow-up.

assessments, but no significant differences between assessments at 2, 6 and 12 months.

To derive scores of items gained since baseline, the items at baseline were subtracted from items at 2, 6 and 12 months to indicate new items attained. At 6 months the FF group had gained three items as against 1.6 items in the HB group ($t = 2.1$, d.f. 28, $P < 0.05$, two-tailed). By 12 months, the difference (3.2 items gained by the FF group compared with 2.3 items gained by the HB group) was no longer significant.

The prediction of Hypothesis 2 was that husbands would be more symptomatic at 2 months. Leeds depression and anxiety scores of husbands stayed low and approximately constant in both FF and HB groups, with mean levels staying between 2 and 5 on both scales in both groups. Analysis of variance on these scores showed no significant effects of time, of FF versus HB condition, or of the interaction, in either depression or anxiety scores. Nor were there any significant *a posteriori* differences between specific means.

According to Hypothesis 3, husbands' depression early in therapy should correlate negatively with wives' gains at 6 months. First, taking husbands' depression at 2 months and wives' Items Gained at 6 months, the product-moment correlation over all subjects was $r = -0.36$ (d.f. 28, $P < 0.05$, one-tailed). In the FF and HB groups, r was -0.52 and -0.32 respectively. Adding husbands' depression and anxiety scores to produce total symptom scores made no substantial difference: the overall correlation rose to $r = -0.39$. Correlations between husbands' depression at 2 months and wives' raw Item scores at 6 months were slightly lower, $r = -0.31$ ($P < 0.05$). At baseline the association between husbands' depression and wives' Item scores was $r = 0.09$ over all subjects. Husbands' baseline depression correlated with wives' 6-month Items Gained at $r = -0.14$ (NS). These subsidiary correlations indicate that it was mainly the change in some husbands' depression in the first 2 months, rather than any association at baseline, that predicted their wives' progress.

According to Hypothesis 4, patients who saw their husbands as more controlling would be more affected by their husbands' depression. For the high perceived control set ($n = 16$), correlations between husbands' depression at 2 months and wives' Items Gained at 6 months was $r = -0.42$ (d.f. 14, P approx. 0.05). For the low perceived control set the correlation was $r = -0.20$ (d.f. 12, NS).

Hypothesis 5 predicted replication of Hafner's 1977*b* finding that the more hostile clients would do worse in therapy. The mean of the Items Gained by the more hostile patients ($n = 14$) was 1.75 by 6 months, and by less hostile patients 2.67. Thus, there was a difference but it was not significant ($t = 1.24$, d.f. 28, P approx. 0.1). The mean of the anxiety scores in the more hostile patients at 6 months was 11.36, and for the less hostile patients 11.50 ($t = 0.9$, d.f. 28, NS).

Patients meeting the criterion of perceiving their husbands to be more controlling, and those meeting the criterion of being more hostile were scattered evenly between FF and HB groups.

As may be seen from answers to the Response to Treatment Questionnaire, Table II, most clients were satisfied with the programme, and most rated themselves as improved on the factors asked about.

TABLE II

Positive responses to questions on the post-treatment questionnaire

	Number of positive responses FF group (n = 14)	*HB group (n = 14)*	*Overall percentage of positive responses (n = 28)*
Satisfied and very satisfied with programme	12	12	86
More and much more easy to go out alone	10	11	75
More and much more easy to go out accompanied	11	9	71
Less and much less depressed	6	8	50
Less and much less anxious	10	9	68
More and much more optimistic	11	12	82

Discussion

Overall neither husbands nor women friends were significantly better in assisting the agoraphobic women to go out more. Nor was either kind of co-therapist clearly superior in helping the remission of anxiety symptoms. In this respect our results resemble those of Cobb *et al* (1984) who found that, of women undertaking the treatment of Mathews *et al* (1981*a*,*b*), those whose husbands acted as co-therapists did no better than those without co-therapists. In terms of the amount of time spent out alone, our results are also comparable with those of Mathews *et al* (1977), who state that the mean time that subjects spent out alone approached, but did not reach, an hour a day. For our subjects the mean time spent out alone rose from 13 minutes a day at baseline to 53 minutes a day at 12 months.

There was a non-significant trend towards the FF group doing better on the behavioural diary measure. The FF group was significantly better ($P<0.05$) in Items Gained at 6 months, but by 12 months the difference was no longer significant. This may have been because the HB group had continued to improve while the FF group had not. Taking all the results up to 12 months it seems safest to conclude that the partial relapse of the HB group at 6 months was due to chance in a syndrome which has wide temporal fluctuations (Buglass *et al*, 1977).

On Leeds anxiety scores neither group was superior (Fig. 2), though the HB group improved slightly more.

Overall the somewhat larger behavioural gains of the FF group might imply that husbands had less interest in increasing their wives' mobility than did women friends. We had the impression that some of the women friends were better as co-therapists than most of the husbands. Certainly there was more novelty for women who had a friend helping them. They gained extra support and perhaps more understanding from another woman.

The claim of Hafner (1977*b*) that husbands would become symptomatic was not replicated. On average, husbands did not become significantly more depressed or anxious at any time.

We were careful to avoid provoking husbands' jealousy or feelings of exclusion. We warned each couple beforehand of possible readjustments to their marriage. We did not accept in the study couples in which the husband was not willing to act as co-therapist. Two couples were excluded because of husbands' hostility and refusal at this point. We encouraged couples to discuss changes that occurred between them. Though important therapeutically, these steps probably diminished the effect we were studying, so the study provided a severe test of Hafner's hypothesis.

In designing the study, we planned to test Hypothesis 3 only by exploring correlations between husbands' depressive symptoms at 2 months and wives' Items gained at 6 months, to avoid too many significance tests on limited data. These correlations showed that those husbands who were more depressed at 2 months had wives who had gained fewer new behavioural items by 6 months. Over all 30 couples the correlation ($r=-0.36$) accounts for only 13% of the variance of Items Gained, and even the larger correlation ($r=-0.52$) in the FF group accounts for only 27% of the variance.

Perceived control and hostility which were predicted to increase the effect (Hypotheses 4 and 5) had small influences.

Therefore, we concluded that there was an effect of the kind that Hafner described, but that its size was modest. In this study, it principally took the form of husbands being slightly less effective as co-therapists than women from outside the family; and of wives whose husbands became more depressed in the first two months of therapy going out less than those whose husbands became more cheerful. No husbands became suicidal and no marital separations occurred during the year of the study.

Becoming depressed is only one possible type of influence. Several other kinds of pressure apart from onsets of symptoms did occur. For instance, one woman started a part-time job, which she liked, but her husband made her give it up. Another husband, perhaps hoping to enhance her enjoyment of being at home, had an elaborate new kitchen built for his wife early in her therapy. In another couple, the husband decided that therapy was making his wife worse despite her going out more and sent her to another clinician who gave her a course of flooding, following which she relapsed below her baseline scores. Clinical intuition about family homeostatic processes may, therefore, often be correct. The difficulty is in casting it into an empirical form. Though this trial specifically estimates the extent of resistance associated with depressive symptoms in the non-treated partner, a composite index is needed. Measures of hostility, of husbands' symptoms, or of any other single parameter may each be relevant in only a proportion of marriages.

We found nothing to negate the principle of including spouses in therapy for agoraphobia. Indirectly our results imply that including the spouse is important, as stressed by Webster (1953). For many couples change does require readjustment in the relationship. But the small negative effects for husbands are outweighed by gains in mobility for the patients.

The results also indicate something of the nature of agoraphobia as a chronic anxiety state. Most subjects went out more. Some began to use public transport. Many went on long visits, and seven (23%) started paid jobs. Most were pleased with their progress (Table II) and anxiety levels decreased. But despite this they remained anxious people (Fig. 2). At 12 months, 27 were above the case level of Snaith *et al* (1976) on the Leeds anxiety scale (between 6 and 7) as compared with 29 at baseline.

The principal effect of this behavioural therapy was that more of the environment was made relatively safe. This kind of therapy leaves largely unsolved the problems of allowing comfortable levels of anxiety to be attained.

Acknowledgements

D. Hodgson thanks the Medical Research Council for a research training scholarship that supported his part in this work. We are grateful to Philip Dodgson for overall clinical supervision of this project, to the self-help organisations that allowed us to contact subjects, to the patients, their husbands and the women who acted as co-therapists for conducting this therapy and providing the data.

Point of View

The Concepts of Mild Depression

R. P. SNAITH

The term 'depression' is now used to cover a wider range of emotional disturbances than was the case when psychiatrists confined their attention to patients referred to psychiatric hospitals. There is considerable confusion about the variety of meanings and the loose terminology leads to claims and counter-claims about aetiology and treatment. The current classificatory systems and the variety of rating scales do not clarify issues concerning appropriate management. The guidelines for a clearer definition of a biogenic form of the concept of depression, which is likely to respond to antidepressant drug therapy, would be of considerable value to psychiatrists, non-psychiatric physicians and others who try to treat or help people in states of disordered emotion. Such guidelines are proposed.

Depression is one of the great themes of psychiatry; in addition to psychiatrists, a considerable number of people attempt to treat, counsel or otherwise help other people who are said to be suffering from depression; yet the concept of the state is obscure. There is little confusion about the recognition of a severe state, sometimes called a psychosis, but *milder* degrees of the condition lack definition. Sometimes the term depressive neurosis is used but Klerman *et al* (1979) have pointed out that a variety of concepts are associated with this term: stress precipitation, maladaptive personality patterns, unconscious conflicts, 'non-psychotic' symptoms; hence the term is so vague as to be useless if not frankly misleading. Kendell (1969, 1976) has argued, from a number of sources of evidence that the only reliable distinguishing feature between depressive psychosis and depressive neurosis is that of the severity of the disorder.

Some historical considerations

The term 'depression' was occasionally used by the early students of mental disorder, and by the end of the nineteenth century attempts were made by some psychiatrists to define states of depression; for instance one early British teacher (Bevan Lewis, 1899) wrote: "In simple pathological depression . . . the patient exhibits a growing indifference to his former pursuits and pleasures: the ordinary duties of life and business become irksome and devoid of interest: especially do all forms of mental exertion cause ennui and disaster . . . and the environment fails to call up pleasurable associations—a dreariness and gloom pervade the outside world, since it is interpreted in terms of the predominant feeling . . .". However, so far as institutional psychiatry was concerned the concept of 'Melancholia' was dominant and the history of this has been recorded by Lewis (1934) who recognised the term as: "Suffering many mutations, at one time the tenacious guardian of outworn schemes or errant theories; presently misused, cavilled at, disposessed, it has endured into our own times, a part of medical terminology no less than of common speech". The word 'depression' was not widely used until the second decade of this century and Alexander Walk (personal communication) wrote: "The word 'depression' only appears once in the Indexes of our Journal before 1909; this is a review of Clouston's Annual Report from Morningside for 1890, where he wrote that states of depression are becoming as common as exaltation as causes of admission to the asylum". ['our Journal' is *The Journal of Mental Science*, forerunner of *The British Journal of Psychiatry.*] It was Adolf Meyer (1905) who started the widespread adoption of the term and, curiously, this was in order to try to eliminate the confusion surrounding the use of the word melancholia: "If, instead of melancholia, we apply the term depression to the whole class, it would designate in an unassuming way exactly what was meant by the common use of the word melancholia and nobody would doubt that, for medical purposes, the term would have to be amplified so as to denote the kind of depression. In the large group of depressions we would naturally distinguish our cases according to etiology, the symptom-complex the course of the disease and the results". Alas, Meyer's hopes have remained unfulfilled in the subsequent eight decades. In fact the confusion worsened and Ascher (1952) commented: "There appears to be a good deal of confusion in the literature, as well as in practice, about depressive illness which is a left-over from the era of descriptive psychiatry. Concepts of psychogenesis, endogeny, reactivity, neurosis, psychosis and others have been introduced to clarify the issue . . . without producing the desired result".

If we now leave the domain of institutional psychiatry and consider the manifold states of human misery which are all sometimes called 'depression', we are in an even more confusing area. Here are the states of grief at loss, frustration of failed aspiration, the gloom of despair, the accidie of disillusion, the demoralisation of long suffering and the cynical outlook of the pessimist. Recently, in the wake of a new psychotherapeutic endeavour, cognitive therapy, there has been an interpretation of 'depression' as a lifelong habit of self-depreciation. Also in this confused field, is to be found the mild state of the biogenic disorder, also called 'depression' but so lacking in definition that it is widely overlooked. This is the state for which Kräupl Taylor (1966) regretted the absence of a term, a 'hypomelancholia' by analogy with hypomania: "Unfortunately this term is not in common use; instead such vague and theoretically misleading expressions as 'mild depressive reaction' or 'neurotic depression' are employed".

Definitions of terms

In the Present State Examination manual Wing and his colleagues (1974) have provided the most succinct definitions of psychopathological terms and, in order to clarify the issues of terminology the definitions of those terms relating to depressive states are set out here.

Depressed Mood
Depressed mood may be expressed in a number of ways—sadness, misery, low spirits, inability to enjoy anything, dejection. . . . The extent to which the subject has cried during the past month is one criterion of severity although it is not sufficient in itself (the deepest depression may be frozen misery which is beyond tears). Another criterion of severity is lack of variability; moderate forms of depression tend to come and go more than severe forms.

The authors state that depressive apathy and other forms of unpleasant affect e.g. nervous tension or anxiety should not be included in the concept of Depressed Mood.

Recent Loss of Interest
There is a definite recent diminution in the subject's interests, either some interests have been dropped, or the intensity of the interest has decreased. Everyone has interests of some sort but the extent of the diminution must be measured in the context of the range and depth of the subject's usual activities. Take into account everyday taking an interest in clothes, food and appearance, keeping up to date with news, etc. . . .

Self-Depreciation
The subject feels inferior to others, even—in the most intensive form of the symptom—worthless. . . . Ideas of self-depreciation are an exaggerated form of self-knowledge about part of the subject's own character, which gives a false picture because it is not balanced by the recognition that most human beings have similar faults. Self-depreciation implies a raising of the standard applied to the subject without an equivalent raising of the standard applied to others, or taking into account balancing merits . . .

Hopelessness
The subject's view of the future is bleak and without comfort. Two degrees of intensity are distinguished by whether the subject has given up attempting to cope, because he can see no point in trying because the future is hopeless. . . .

Observed Depression
Rate a sad, mournful look with tears in the eyes and gloomy monotonous voice. . . .

In addition to these items there are definitions for *Neglect Due to Brooding*, *Subjective Anergia*, *Slowness and Underactivity*, *Inefficient Thinking*, *Poor Concentration*, *Suicidal Plans or Acts*, *Morning Depression*, *Social Withdrawal*, *Guilt* and other related symptoms. The manual must be consulted for full definitions. It is evident that authors of the PSE have provided a valuable service by these definitions but even so it may be noticed that the definition of *Depressed Mood* is less precise than the other symptoms and covers, in fact, a range of concepts.

The nosological systems

Two widely used systems are the International Classification of Diseases, at present in its ninth revision (ICD-9: World Health Organization, 1978) and the third revision of the Diagnostic And Statistical Manual (DSM-III: American Psychiatric Assocation, 1980).

The ICD-9

Preview of the proposals for revision leading to ICD-10 indicate that the term 'depressive neurosis' will be abolished and depressive states will no longer be defined partly in terms of their supposed aetiology. However no substantial revision of the following comments is required). The glossary to the Mental Disorders Section of this system provides a convenient guide (p. 58) to the categories in which depression is a major or significant feature. There are 10 three-digit and 19 four-digit categories. In order to understand the guidance provided for classification the significant parts of the definitions are listed:

295.7 *Schizoaffective Type*
A psychosis in which pronounced manic or depressive features are intermingled with schizophrenic features . . .

296.1 *Manic-Depressive Psychosis—Depressed Type*
An affective psychosis in which there is widespread mood of gloom and wretchedness with some degree of anxiety . . .

298.0 *Other Non-Organic Psychosis—Depressed Type*
A depressive psychosis which can be similar to 296.1 but is apparently provoked by saddening stress such as bereavement or severe disappointment or frustration . . .

300.4 *Neurotic Depression*
A neurotic disorder characterized by disproportionate depression which has usually recognisably ensued on a distressing experience; it does not include among its features delusions or hallucinations and there is *often* preoccupation with psychic trauma which preceded the illness e.g. loss of a cherished person or possession. Anxiety is also *frequently* present; mixed states of anxiety and depression should be included here . . . [My italics]

301.1 *Affective Personality Disorder*
. . . is characterized by lifelong predominance of pronounced mood which may be persistently depressive . . .

308.0 *Acute Reaction to Stress Predominant Disturbance of Emotions*
Panic states, excitability, fear, depression and anxiety . . .

309.0 *Adjustment Reaction: Brief Depressive Reaction*
States of depression, not specifiable as manic-depressive, psychotic or neurotic, generally transient, in which depressive symptoms are usually closely related in time and content to some stressful event.

309.1 *Adjustment Reaction: Prolonged Depressive Reaction*
States of depression, not specifiable as manic-depressive . . . generally long lasting; usually developing in association with prolonged exposure to a stressful situation.

311 *Depressive Disorder Not Elsewhere Classified*
States of depression, usually of moderate but occasionally of marked intensity, which have no specifically manic-depressive or other psychotic depressive features and which do not appear to be associated with stressful events or other features specified under neurotic depression".

313.1 *Disturbance of Emotions Specific to Childhood And Adolescence; With Misery And Unhappiness*
. . . the main symptoms include misery and unhappiness . . .

Surveying these definitions it is clear that the word 'depression' is introduced into most of them without further qualification or definition; the two exceptions are the manic-depressive psychosis where the mood is described as one of "widespread gloom and wretchedness" and the emotional disorder of childhood characterised by "misery and unhappiness". For the rest it seems that the user is free to include any concept of the term depression that he wishes. The definition of Neurotic Depression is particularly vague and there are so many generalisations that the only certain statement is that symptoms of delusions or hallucinations preclude the diagnosis.

The DSM-III

(This paper was written before the proposals for revision were seen by the author. Inspection of the draft for DSM-III-R indicates that major revision of the following comments is not necessary). In this system the terms neurosis and psychosis have been abolished and diagnostic categories are independent of supposed aetiology. Depressive disorders are defined in the terms of the prevailing symptoms, their intensity and their duration. These are classified under the major category of Affective Disorders into Major Affective Disorders, Other Specific Affective Disorders and Atypical Affective Disorders. (The authors are apologetic about the use of the German word *Affekt* instead of the English word Mood but state that tradition has made this inevitable). Apart from the Affective Disorders there is only one other category in which the word 'depression' is used and that is *309.00 Adjustment Disorder With Depressed Mood.*

296.2 *Major Depressive Episode*
For this category to be correct the subject must experience one of two alternative symptoms and experience four other symptoms from a list of eight. The first two symptoms are: 'dysphoric mood' and 'loss of interest in all or almost all usual activities and pastimes (anhedonia). Dysphoric mood is defined by a choice of epithets: depressed, sad, blue, hopeless, low, down in the dumps and (surprisingly) irritable. The list of eight symptoms, of which four must have been present nearly every day for at least 2 weeks (in children under 6, at least three of the first four) are: a) poor appetite or significant weight loss or increased appetite and significant weight gain; b) insomnia or hypersomnia: c) psychomotor agitation or retardation; d) loss of interest or pleasure in usual activities or decrease in sexual drive; e) loss of energy, fatigue; f) feelings of worthlessness, self-reproach or excessive inappropriate guilt; g) diminished ability to think or concentrate; h) recurrent thoughts of death, suicidal ideation or attempt.

The category can be further classified as 'With Psychotic Features' when either mood congruent or mood incongruent psychotic features are present or as 'Melancholia' if some of the symptoms are of more severe degree and there is evidence of diurnal variation of mood. It should be noticed that anhedonia appears in both sections of the definition so making it unlikely that the category could be correctly applied in the absence of that symptom.

Two other categories of affective disorder depend upon symptoms of lesser severity than Major Depressive Episode and chronicity. These are:

301.13 *Cyclothymic Disorder.*
During the past two years numerous periods during which some symptoms characteristic of both the depressive and the manic syndromes were present but not of sufficient severity and duration to meet the criteria for a Major Depressive or Manic Episode. . . .

The disorder must not be simply a partial remission of bipolar disorder.

300.40 *Dysthymic Disorder*
It is recognised that this may be termed depressive neurosis in other classificatory systems. The disorder must have been present for two years; it usually commences at a young age; chronic physical illness or psychosocial stresses, personality disorder or an affective disorder which does not fully remit are predisposing factors; the symptomatic criteria are the same two mandatory alternatives as in Major Depressive Disorder and then three of a list of 13 accessory symptoms must be present.

296.82 *Atypical Depression*
This is a residual category for individuals with depressive symptoms who cannot be diagnosed as Major or Other Specific (Cyclothymic or Dysthymic) or Adjustment Disorder.

The DSM-III provides fairly well defined criteria for categorisation but unfortunately a heterogeneous group of individuals may be included under each of the categories.

A further problem with the category Major Depressive Episode is that many physically sick individuals could be included simply on account of their physical illness and without the necessity to postulate a presence of a mental disorder; thus depressed mood, loss of appetite or weight, insomnia, loss of energy, loss of sexual drive and recurrent thoughts of death may all occur in serious physical illness. This failing, widely overlooked, is examined by Kathol and Petty (1981). The inconsistencies arising from different definitions of depression have been studied by Sashidharan (1985).

Individual Diagnostic Systems

Research findings and the possibility of extrapolation of meaning to other contexts is seriously hampered by the variety and imprecision of diagnostic systems and also by the adoption system individual to a particular research group. Space allows only one example of such an individual system which is, however, selected on account of the fundamental questions and conclusions about the nature of depression arrived at by the leader of the research team, Professor George Brown and his associates. The criteria for 'case' and 'borderline case' of depression are based on the Present State Examination symptoms (Finlay Jones *et al*, 1980). For a case Depressed Mood is mandatory and then any four of a list of ten symptoms: Hopelessness, Suicidal Ideas or Actions, Weight Loss, Early Waking, Delayed Sleep, Poor Concentration, Neglect Due to Brooding, Loss of Interest, Self-Depreciation, and Anergia. Symptoms must have been present for 2 weeks but there are no clear criteria of severity. Given the difficulties, already noted, in the PSE definition of Depressed Mood it is therefore clear that these criteria constitute a very wide trawl into which large numbers of sick, poor or unhappy people may be caught up. It is perhaps not surprising that Brown and his colleagues find this state they define as 'depression' to be related to social and personal disadvantage and also to have a high prevalence.

Rating scales

Many research studies have based the definition of a 'case' of depression on a certain score having been attained on one or other of the large number of depression rating scales. The different construction of these scales, and their individual characteristics of item array, cause serious difficulties in comparing one study using one scale with another using a different scale. The procedure of arriving at a definition of a case by adding up numbers derived from severity grade score of a number of symptoms has a certain attraction until it is realised that one case may be very different from another. As an instance of this, Cooper & Fairburn (1986) found that a group of bulimic and a group of depressed patients had similar scores on the Montgomery-Åsberg Depression Rating Scale but different symptoms, or scale items, contributed strongly to the overall score in the two groups.

The widely used Hamilton Depression Scale (Hamilton, 1967) consists of 17 items: depressed mood, feelings of guilt, suicidal ideation, work and activities, insight, retardation, agitation, insomnia (early, middle and late), psychic anxiety, somatic anxiety, gastrointestinal symptoms, general somatic symptoms, genital symptoms (loss of libido or menstrual disturbances), hypochondriases and loss of weight. The last six of these items are symptoms of somatic disturbance and account for 31% of the possible total score; if the insomnia items, which so often rate highly in physical illness are included, then 42% of the total is accounted for. The Depression Inventory (Beck *et al*, 1961) is another widely used 'depression' scale and again contains a high proportion of symptoms relating to somatic disturbance. Stewart *et al* (1965) pointed out that such symptoms are common in medically ill patients and advised that such assessment scales for depression should be avoided but their advice has largely been unheeded. An improvement on previous scales is the Montgomery-Åsberg Depression Rating Scale (Montgomery & Åsberg, 1979): this scale is oriented toward psychic symptoms and are: apparent sadness, observed sadness, inability to feel, difficulty in concentration, inner tension, pessimistic thoughts, suicidal thoughts, lassitude, reduced sleep, and reduced appetite. However even here 30% of the total score is accounted for by the last three items and all three commonly occur in all illnesses and states of distress, not just depression.

The range of self-assessment scales are popular as screening instruments for the presence of mood disorder. They are open to the same fallacies. For instance Kutner *et al* (1985) studying depression and anxiety in dialysis patients found that scales containing disease related items yielded exaggerated scores. The depression scale they used was the Self-Rating Depression Scale (Zung, 1965); this contains 20 statements, five of which are: 'I have trouble sleeping at night', 'I eat as much as I used to', 'I notice I am losing weight', 'I have trouble with constipation', 'My heart beats faster than usual'. Other items which may well be rated highly by people who suffer from physical sickness or are under some other adversity are: 'I feel that others would be better off if I were dead', 'My life is pretty full', 'I feel I am useful and needed', 'I feel hopeful about the future', 'I enjoy looking at, talking to and being with attractive women/men'. Altogether over half of the items of this widely used depression scale are composed of feelings or symptoms which do not necessarily indicate the presence of a mental illness.

The majority of depression rating scales contain a motley collection of symptoms, attitudes and feelings and will produce high prevalence rates and a large proportion of false positives if case detection relies upon them.

Discussion

In 1984 Mayou pointed again to the well-known fact that lack of agreement on definitions of disorders causes great difficulty in psychiatry. In no area is this more true than in the concept of depression and Andreason (1982) wrote: "Although affective disorders have been recognised for thousands of years, clinicians and researchers have still not reached agreement on the basic concepts of these disorders and the best methods of classifying them". Richmond & Barry (1985) surveyed the confused areas between mental illness and 'normal' states of distress, the large numbers of professional and other workers engaged in these grey areas and the potential enormous waste of resources and misapplication of treatments; they concluded: "Better definitions of clinical disorders must be developed *e.g. differentiating demoralisation from depression.* Psychiatry must clarify the areas where its expertise overlaps with other mental health disciplines (Lowy) and take the initiative in reallocating resources so that the paradox of increasing resources creating additional need can be overcome". [My italics]

Psychiatry is still overconcerned with providing classificatory systems but these too often end as mere pigeon holes into which patients can be placed with their appropriate diagnosis but frequently the diagnosis fails to lead to correct treatment or else treatments are applied blanket-fashion no matter what the diagnosis. In a leading work on depression (Weissman & Paykel, 1971), the authors wrote: "Attempts have been made to isolate within clinical depression two or more types, classified by such labels as neurotic, psychotic, reactive, endogenous. These are of considerable research interest. . . . However their practical application in guiding treatment is still limited".

At the time when psychiatrists confined their attention to patients admitted to mental hospitals there was rarely much difficulty about the diagnosis of the depressive phase of manic-depressive psychosis. This is a severe illness with fairly stereotyped symptomatology; the addition of information from the course of the disorder, the history of mania and familial history leads to fairly certain conclusions about the correct management and treatment. But the situation has now changed in three respects. a) Attention is now paid to the milder mood disorders occurring in the community and non-psychiatric hospital departments; b) workers other than psychiatrists are involved in the detection and treatment or care of people suffering from these mild mood disorders; c) finally, effective treatments, both psychological and pharmacological are now available, or rather such treatments can be effective when applied in the correct circumstances.

At the present time there is a vogue for community studies in the field of depression. Commonly, rating scales or diagnostic systems of one type or another are applied and a high prevalence of 'depression' is revealed. Researchers wonder at the fact that general practitioners, cancer physicians, neurologists and so on should be so inept at diagnosing this treatable condition but all that has happened is that a larger number of people have been declared to be in the company of the mentally ill or in need of some type of psychiatric or psychological treatment which is frequently not specified.

In future, research in this area must rest upon the need to provide more certain guidance on whether or not treatment is required and if so, what form that treatment should take. Now that effective antidepressant drugs are available the next essential task of psychiatry is to provide clear working guidelines of who might reasonably be expected to respond to such prescription, cutting short much misery and confusion and the frustration of other physicians and psychological therapists to help them.

How then may 'depression in this mild form be defined and assessed? One solution would be to stop using the term altogether and to describe states of mind in simple terms: grief at loss, poor self-esteem, demoralisation due to adversity and so on. The American DSM has made a start by reverting to the old term 'melancholia to describe the severe biogenic depressive illness; but what of the milder biogenic disorder, the state which has a high chance of improvement with antidepressant drug treatment, i.e. Kräupl Taylor's 'hypomelancholia'? In this paper I have put forward the reasons why current diagnostic systems are unsatisfactory and are frequently misleading. The wide range of current depression rating scales are also mostly misleading since they are composed of a motley of items on which any sick or unhappy person may score highly. Reliable laboratory tests are not available, possibly because attempts have been made to validate them on poorly defined clinical samples. In any case a laboratory test would have to be very easily conducted to be of real value to the large numbers of people who are involved in the management of 'depression'.

A solution to the problem of defining mild biogenic depression must rest upon the recognition of well defined clinical features which may relatively easily be established as being present or absent. For all the foregoing reasons these clinical symptoms must not include somatic symptoms which may occur in a wide variety of bodily illnesses, nor must a non-specific state such as insomnia and lack of energy be included. Symptoms indicative of severe mood disorder, such as suicidal preoccupation are unsuitable for they would lead to a high false negative rate. Referring again to the list of symptoms in the DSM definition of Major Depressive Disorder, what remains? There remain: depressed mood (dysphoria) loss of pleasure response (anhedonia), psychomotor retardation or agitation, feelings of worthlessness, self-reproach, inappropriate guilt, and diminished ability to think or concentrate. Two further symptoms from the list of 'depressive' symptoms in the PSE may be considered: hopelessness and neglect due to brooding, although both have implications of a severe disorder.

Kräupl Taylor described the essential hypomelancholic symptoms: "There is usually a decrease in mental and physical activity, in self-confidence and in the enjoyment of pleasure. The patient lacks energy and initiative in general". Another student of mild biogenic depressive disorders is Klein (1974); he recognised that stress sometimes was a factor in the precipitation of depressive states which were nonetheless to be considered biogenic in terms of having a high likelihood of response to antidepressant drugs, and so he coined the term 'endogenomorphic depression' and described the pathognomonic feature of this state: "A sharp, unreactive, pervasive impairment of the capacity to experience pleasure or to respond affectively to the anticipation of pleasure".

Which features then may be taken to be pathognomonic of the mild biogenic depressive state? Depressed mood is too diffuse a concept, too ill-defined as witness the number of epithets which may be provided to substitute for it. Feelings of worthlessness and guilt are too liable to have a basis in reality i.e. to be psychogenic; hopelessness may also be based upon the undeniable situation of the person and therefore unreliable as an indicant of biogenic depression. Psychomotor retardation is a reasonable proposition, a feeling of being slowed in thought and action; but in many patients prominent anxiety is present and agitation not retardation is the experience; moreover retardation is too liable to be a symptom of physical diseases, such as parkinsonism or arthritis, to be a reliable guide to the presence of biogenic depression in the setting of physical illness.

Of all the states anhedonia emerges as the central and reliable symptom of hypomelancholia. Anhedonia, the loss of ability to experience pleasure may also be fairly reliably ascertained by a few key questions: does the sight of flowers or a beautiful sunset lift the heart or the sound of one's favourite music make one want to sing with it? Can one anticipate with pleasure, look forward to a usually enjoyed event such as a weekend outing or a visit from a friend? Does one still pursue old hobbies or pastimes with real pleasure or does one simply do them for the sake of doing something or to put on appearances? And can one still enjoy a good joke with real mirth?

Some time ago we were asked by a physician to help him sort out, in his busy medical practice, which of his patients were just unhappy, demoralised or miserable for some other reason and which may be helped by the prescription of an antidepressant drug. As a result of this exercise we devised the Hospital Anxiety And Depression Scale (Zigmond & Snaith, 1983); this is fully described elsewhere but the essential feature is a subscale called 'depression' which comprises seven items: one is a 'dysphoria' item—I feel cheerful—and another a retardation item, but the essential basis is anhedonia and the other five items describe this experience in one form or another. The scale therefore measures anhedonic depression which we take to be the best indicant of hypomelancholia and we advised our colleagues to consider prescribing antidepressants if a high score appeared in this scale. Kendell (1982) advised that two or more criteria should be used when selecting subjects for biological research in mental illness and I also advocated the combined use of both a researcher administered and a self-assessment scale (Snaith, 1981).

The definition of the ubiquitous states that masquerade under the term 'depression' is of central importance and no real progress will be made in research and the development of clear guidelines to effective intervention until this is done. Considering the vastness of the sea of human unhappiness and the huge numbers of people attempting to fish souls out of it, this definition is perhaps the most urgent problem demanding solution by psychiatrists. In this essay I have developed the view, based upon examination of the work of others and on my own clinical experience, that anhedonia, if it is persistent and not adequately accounted for by the person's circumstances is at present the nearest guide to the biogenic depressive disorder. This suggestion needs to be put to the test of critical research.

Brief Reports

Case Report: Severe Depressive Illness in the Context of Hypervitaminosis D

Hypercalcaemia, whether due to undiagnosed hyperparathyroidism or some other cause, can lead to clinical depression. The patient described here developed a severe depressive illness in the setting of hypervitaminosis D after 15 years of inappropriate therapy with calcium gluconate and strong calciferol. The importance of monitoring serum calcium levels in anyone on vitamin D therapy is stressed.

It has been known for some time that hyperparathyroidism may present as a psychiatric disorder varying in type from a minor depression to frank psychosis and even catatonic stupor (Paterson, 1974). Karpati & Frame (1964) studied 14 cases of primary hyperparathyroidism and noted that 42% of the patients had subjective or objective neuropsychiatric manifestations. These were of such a severe nature in four of the cases that a neurological or psychiatric consultation was obtained. Reinfrank (1961) described a case of hyperparathyroidism that presented with depression of such severity that a course of ECT was contemplated. In Petersen's (1968) series of patients with hypercalcaemia, mostly arising from hyperparathyroidism, 36% showed mental changes such as depression, listlessness and lack of initiative and, sometimes, irritability and explosive outbursts. Flanagan *et al* (1970) described a large family suffering from familial hyperparathyroidism, where psychiatric features were prominent. The severity of psychiatric signs correlated with the degree of hypercalcaemia in each case.

The reason for emotional disturbances in hyperparathyroidism is not yet clear. Gatewood *et al* (1975), however, feel that the hypercalcaemia is basically responsible because of the general dampening effect that high blood levels of calcium have on neurological function. According to Lishman (1978) the cause of any psychiatric disorder lies chiefly with the elevation of the serum calcium.

Hypercalcaemia from any cause can give rise to disabling symptoms such as fatigue, malaise, thirst and polyuria (Fourman & Leeson, 1959). Other common symptoms include anorexia, nausea and vomiting and constipation.

One well recognised cause of hypercalcaemia is excessive therapy with vitamin D or one of its analogues. Karpati & Frame (1964) describe 13 cases of hypercalcaemia arising from causes other than hyperparathyroidism. Three of these resulted from vitamin D intoxication. Paterson (1980) in a recent survey describes 21 patients who suffered from vitamin D poisoning. Nine of these cases presented with fatigue or confusion or both (Paterson, personal communication). Paterson emphasised that vitamin D is a cumulative drug so that the plasma calcium level at any particular time represents the combined effect of therapy given over a period of several months. Vitamin D is stored for long periods in both adipose tissue and muscle.

Carman & Wyatt (1979), in a double-blind study, observed that patients with a history of periodic psychoses experienced relapses 2 weeks after being started on dihydrotachysterol (DHT), a synthetic analogue of vitamin D, which causes rises in both serum calcium and serum phosphate.

Case report

The patient, a 58-year-old woman, was referred for an urgent psychiatric opinion as she had stated that she felt she could no longer carry on and she wished to die. At interview the patient sat in a languid, drooping fashion in an armchair. She presented as a pale, pathetic and thin figure. Her speech was retarded and delivered in a monotone. Much of the patient's thought content was morbid. Shortly before admission she had retired to bed each night hoping she would never wake up.

For many years she had been troubled with constipation and lower abdominal discomfort. Various laxatives had been tried without effective relief. She stated her general misery as follows: 'I know I am dying, because I have been constipated so long and I can't take any more pills for the trouble.' Insomnia, affecting all parts of the night, had been a further feature.

During the previous 2 months, the patient had lost 7 kg in weight. She had been aware of loss of appetite, and occasionally nausea, for a considerable time before this. There had been accompanying difficulty in swallowing foods and her diet comprised fluids or semi-solids. In view of the patient's state of deep depression, and her frail physical state, immediate admission to the local psychiatric hospital was arranged.

From the psychiatric point of view, the patient was extremely depressed and her mood was noted to be unaffected by external events. Because of her excessive dependence on her husband the patient had felt extremely guilty about the effect that her condition was having on him. She was also extremely anxious that some calamity might befall her husband and in that event she would be unable to cope. A loss of self-respect had been present for some time and the patient said she was ashamed that she was no longer able to keep up her usual tidy appearance or do her hair properly. There was a considerable degree of psychomotor retardation. The patient frankly said that life was not worth living and she would be better away from it all. There was no evidence of thought disorder, delusional thinking or hallucinations. With respect to her memory, the patient was able to give a reasonably consistent and clear history and there was no evidence of memory defect on formal testing. She did admit, however, that she had recently had a tendency to mislay things. She herself put this down to periodic failure of concentration. There was some degree of diminished concentration. Orientation was correct in all respects. The patient's level of consciousness was diminished, resembling that seen in pre-stuporose states.

Normally an avid reader of novels, she had been, of late, unable to read either books or newspapers. Routine tests for intellectual functions were administered but showed no evidence of organic brain damage. There was an awareness of recent events and she appeared to be of average intelligence.

Physical examination revealed recent evidence of weight loss. The patient weighed 44.5 kg (height 166 cm). There was marked facial pallor and also signs of anaemia in the tongue and mucous membranes. The physical examination was otherwise unremarkable apart from the presence of a laparotomy scar.

The patient, an only child, had a middle income background. There was no history of neurotic traits during the patient's development years. Her schooling was marked by achievements, both academic and social. After leaving School, she worked as a shorthand typist before her marriage. She had no children. The patient and her husband had marked interpersonal difficulties. The husband worked in a job which he loathed and possibly, partly as a result of this, he had been abusing alcohol for some time. Interviewed at the time of his wife's admission to hospital, the husband appeared to be unaware of how unwell his wife had been.

For 10 years the patient had suffered from periodic agoraphobic symptoms for which she had received both behaviour therapy and a course of clomipramine.

The patient's first serious physical illness had been 29 years earlier when she developed thyrotoxicosis. Her principal symptoms were exhaustion, emotional lability and a choking sensation on lying down. Partial thyroidectomy was done. There was an episode of post-operative tetany.

The patient experienced alopecia areata 6 years later. This was thought to have been of emotional origin. Five years later a D & C was carried out for menopausal menorrhagia. A further 3 years later, the patient was referred to a physician because of complaints of tiredness and feelings of panic when out shopping. A physical examination and extensive tests were all negative apart from a marginally reduced serum calcium (2.10 mmol/litre). It was suggested that this hypocalcaemia had occurred as a result of the removal of parathyroids at the time of the thyroid surgery. She was put on calcium gluconate tablets 600 mg *t.d.s.* and strong calciferol tablets 1.25 mg each day. She remained on this medication till the occasion of her in-patient psychiatric treatment 15 years later.

At the time of her admission to hospital the most striking abnormality was that of an elevated serum calcium 3.12 mmol/litre (normal range 2.15–2.65 mmol/litre) and a lowered serum phosphate 0.48 mmol/litre (normal range 0.8–1.55 mmol/litre). Serum electrolytes, blood urea, blood glucose, serum albumin, liver function tests and T4 were within normal limits. Haematological values were as follows: haemoglobin 9.4 g/dl, PCV 0.30, MCHC 31.5%, MV 97 fl, WBC 10.7×10^{12}/l, ESR 15 mm/h (Westergren). Blood film revealed normocytic to slightly macrocytic RBCs which were normochromic. Some elliptocytes were seen. There was marked thrombocytopenia. Leucocytes were in normal proportion. Serum B12 and folate were within normal limits. Faecal occult blood was positive on two out of three occasions. The chest X-ray was reported on as follows: "The heart is not enlarged. There are numerous calcified foci in the left lung field. The lung fields appear otherwise clear." A barium swallow and follow through, as well as a barium enema, were normal.

It was considered that the patient's depressive illness, which was essentially of the endogenous variety, had occurred in response to the abnormally high levels of blood calcium. Both the calcium gluconate tablets and the strong calciferol tablets were discontinued after the patient's admission to hospital. The blood calcium and phosphate levels were checked regularly. The former reached normal levels after 9 weeks, the latter after 6 weeks. She remained depressed and lethargic until 3 weeks following admission. At that stage the serum calcium had dropped from 3.12 mmol/litre to 2.94 mmol/litre. Improvement, both physical and emotional, started about this point and continued throughout the rest of her 2-month stay in hospital.

Medication comprised oral iron therapy, a hypnotic periodically and laxatives. By the end of her hospital stay the haemoglobin level had raised slightly to 9.9 g/dl. She was discharged on no medication.

Follow up for 1 year from both the psychiatric and medical point of view revealed no serious problems. Her mood remained stable and the serum calcium levels remained within normal limits. Sadly, 6 months after that follow up she had a further episode of depression and drowned herself. Despite this it was felt that the short-term response to correction of the plasma calcium was worthwhile.

Discussion
